According to E. von Cyon*, the effect of the remedy on the vasomotor system is central and *not* peripheral. With him on this point are Cybulski and Szymonowicz. Oliver and Schaefer, however, declare that the effect is peripheral. A writer in "International Clinics" for 1900 briefly sums up thus: "hypodermatically it causes a distinct but temporary rise in blood pressure;" while O. F. Grünbaum,† in recommending the internal administration of the gland in hæmatemesis, says that there is "no sensible rise in blood pressure noted." This matter will, of course, have to be settled by careful scientific observation, due attention being given to the procuring of a uniform drug or of a definite active principle, as, for example, epinephrin, described by Abel.

In the meantime the value of the suprarenals as a therapeutic agent will occupy the attention of clinical observers.

As is well known, the rhinologists have already made use of the property possessed by the aqueous extract of suprarenal powder, of causing contraction of the arterioles of the mucous membranes when applied locally.

It has already achieved a place as a hemostatic, albeit a tendency to secondary hemorrhage exists. Nevertheless, the respite obtained by the exhibition of the gland enables the operator to secure his patient against further loss of blood.

In pulmonary hemorrhage the value of the remedy has been pointed out by Kenworthy,‡ and since corroborated by other observers.

After having observed the rapid work of suprarenals in a case of severe pulmonary hemorrhage, I was encouraged to treat two cases of senile pneumonia with the same remedy. In the one case (Case II) the bloody sputum, almost fluid, was rapidly checked within a few hours, and a rapid recovery ensued. Case I was complicated by a coincident acute nephritis following diabetes mellitus.

In these, as in other, cases the heart reacted quickly, and steadied itself with reduced pulsation. The same results have been attained in cases other than pneumonia. For instance, in a case of asthma with co-existing albuminuria in a patient seventy-eight years of age, a pulse of 100, thready and hard, dropped in a few hours to 82, accompanied by the disappearance from the sputum of the blood which had been present for hours. In this case the albuminuria also disappeared after the second day.

I conclude from my observations of the remedy that we have a most valuable heart stimulant, which we are at liberty to use in the presence of impending heart failure, impeded pulmonary circulation, as in pneumonia, and with coexisting renal inflammation.

I have noted peripheral increase of blood pressure in a few instances, but the sign was not permanent.

I append a few cases which will illustrate the action of the drug:

---

* Pflüger's Archiv., 1899.

† *Journal of Physiology*, Vol. XXIV.

‡ MEDICAL RECORD March 16, 1901.

Case I.—Mrs. B., aged sixty-five years, a large woman, corpulent, who had suffered from diabetes for ten years, developed a sharp nephritis in April, 1901. With the appearance of the nephritis there was a disappearance of the sugar in the urine. This condition lasted until early in June, when pneumonia developed.

Symptoms.—Pulse 86, temperature 101°, respiration 30, pain in chest, hoarse cough, rusty expectoration. Examination of the lungs showed the lower third of the left lung to be consolidated. Patient was torpid and indifferent. Strychnia sulph. gr. 1-30 was given with suprarenals every three hours. In thirty-six hours the temperature was normal, pulse lower, patient brighter. No râles were heard over the lungs, and the consolidation steadily retrogressed. The patient died in uremic coma six weeks later.

Case II.—Mrs. A., aged seventy-two years, well nourished and usually healthy, was seized with a chill in May, 1901, which heralded an attack of pneumonia. When I saw her I found her very dull, skin sallow and dry, temperature 103°, pulse 126. Mucus expectorated was thin and mostly lost in blood. Lower half of left lung was found congested, crepitant râles being present, while percussion elicited marked dulness.

℞. Suprarenals gr. iij every three hours. Next day the temperature was 99.5° F., pulse 100. Mind clear and sputum whitish. The treatment was continued for several days. After the third day there was an absence of all symptoms of pneumonia, while the only physical signs were subcrepitant râles and dulness. No crisis was evident.

Case III.—Mr. C. H., aged thirty years, was taken ill on January 12, 1902, with grippe. Temperature 104, pulse 128. The patient had a dilated heart and had suffered from distress on exertion, for four or five years. After three weeks from the onset of the grippe the temperature became normal with a pulse of 84. February 2d he was taken worse with a temperature rise, without chill, to 102°, pulse 124-130, respiration 38. Examination gave marked dulness over lower half of right lung, crepitant râles over lower third of same. Expiratory sounds high pitched, patient's face slightly cyanotic. He was very restless and delirious. In addition to the carbonate of guaiacol suprarenals grs. iij were administered every two hours (chewed). February 3d, pulse had dropped to 90°, temperature 98°, character of râles changed to subcrepitant and moist over the involved area. February 4th, temperature 97.5°, pulse varied from 80 to 100 on slight causation. Suprarenals continued. Temperature remained normal for a week or more, when it began to go up slowly. Areas of bronchopneumonia developed, disappeared, and occurred in both lungs. Cough at times very severe. The heart showed signs of increasing dilatation, and suprarenals, strychnia and [illegible] were freely administered. In spite of the rapid heart action and occasional fever the appetite remained good and the patient gained flesh and strength. However, on the first of February, after slight exertion, he suddenly died, no post mortem.

Case IV.—D. P., Jr., aged seven years, began on February 3, 1902, with grippe, some bronchitis present. Night temperature 101. Sputum contained large number of influenza bacilli. Temperature dropped on second day to normal. Sibilant râles still persisted until February 8. On this date the pulse suddenly went to 140 with temperature of 103°. Child became very dull and apathetic. Crepitant râles were discovered in lower half of right lung, dulness corresponding. Suprarenals gr. iij were given every two hours (chewed), antiphlogistin to chest. After twelve hours the symptoms began to improve, the temperature dropping to 98° and going above 100° for about two hours after midday. Pulse slackened *pari passu* with thermal improvement. Patient was practically well after second day. Dulness persisted for five days. Bronchial râles were gone on the sixth day.

Case V.—Mrs. F., aged seventy-five years, February 13, 1902, was suddenly attacked in the night with severe pain in the chest, right side. Temperature at 10 A.M. 97.5°, pulse 108, respiration 32. Auscultation revealed crepitant râles over lower fourth of left lung, respiratory murmurs sharply accentuated. Over the right lung the respiratory sounds were much subdued.

℞. Suprarenal capsule gr. iij every two hours, to be chewed. P.M., pulse 100, respiration 97, less pain. February 14, no pain, pulse 100, respiration 28, fewer râles, breathing easy. February 15, pulse 78, temperature 98°. Dulness over lower thirds of both lungs. No râles audible. Patient pursued a steady course to recovery.

Case VI.—C. P., male, aged fifty-four years, German. I first saw the patient on February 24, the sixth day of his illness, when the following phenomena were noted: Patient extremely jaundiced, indifferent to surroundings, and delirious. Temperature 100°, pulse 100, soft, respiration 24. Bowels closed, urine very scanty and of a deep red, mouth and skin very dry. Some cough, painful, which brought up a very tenacious prune-juice colored expectoration. Physical examination showed the right lung to be involved as follows: In front crepitant râles up to level of one inch below nipple. Behind, a few crepitant râles at base of lung. Dull percussion noted everywhere save at apex, where it was very hyperresonant.

℞. Salines to relieve the constipation; free water drinking; suprarenals, ichthyol to seat of pain. February 25, pulse 108, temperature 101°, respiration 24; P.M., pulse 120, temperature 102°, respiration 30. February 26, A.M., pulse 96, temperature 98°, respiration 28. On the 25th the sputum became highly bile colored and bitter, pulse became stronger, but intermitted every tenth beat. Bowels became loose and kidneys acted well. Cerebral symptoms disappeared, and jaundice began to disappear. Evening of the 26th, pulse 108, temperature 101°, respiration 32. Evening of the 27th, pulse 92, temperature 98°, respiration 22. A history of cough lasting for a year past was only elicited after this patient's recovery, while with resolution apical signs show an old tubercular focus. It may be held that we had here a crisis, but if so, I feel that the critical period was influenced by the great heart stimulation afforded by the suprarenals.

I have given here but a few of what I might call representative cases illustrating various types of pneumonia, but, although few in number, I trust that they may suffice to point the way to others who may study the remedy.

[illegible] State Street, Chicago.

Mastitis in Typhoid Fever. Thomas McCrae, from his study of this subject concludes that (1) Mastitis is a rare complication of typhoid fever, and usually occurs late in the attack; (2) It occurs in both sexes, and is apparently not associated with a functioning gland; (3) Both breasts are involved in about half of the cases; (4) Suppuration occurs in about half of the cases, and may be associated with the typhoid bacillus or staphylococcus; (5) It is of no special moment in the prognosis.—*Bulletin of the Johns Hopkins Hospital.*

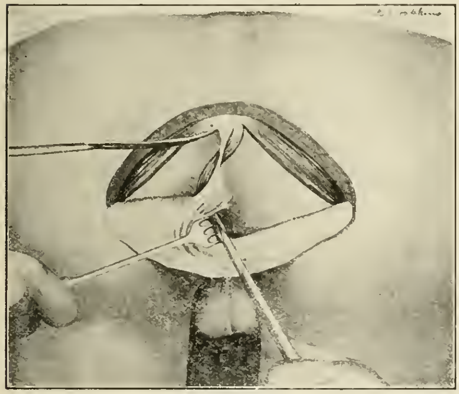
PLASTIC OPERATION FOR RESTORATION OF THE SPHINCTER ANI, WITH REPORT OF A CASE.

By CHARLES H CHETWOOD, M.D.,
ATTENDING SURGEON, BELLEVUE HOSPITAL, NEW YORK.

THE successful result which followed the operation here described, and the novelty of the method should, I think, justify its further trial at the hands of other surgeons.

The patient, who had been suffering from incontinence of fæces of many years' duration, entered Bellevue Hospital, February, 1901. He had been gored in the rectum by a steer, and, in his occupation as cattle-dealer, was injured in the same region on several occasions. He had been operated upon eight or nine times, in an endeavor to restore the continuity of the sphincter muscle, without success. The last operation previous to the one performed by the writer was done according to the Gersunny technic.

The condition of the patient at the time the writer first saw him consisted in absolute inability to retain the fæces, and necessitated the wearing of a mechanical plug about one and one-half inches in diameter. Surface examination revealed little evidence of the existence of an external sphincter. The patient's general condition was good. The writer's operation was performed about one year ago.



The patient being placed in the knee-chest position, a large semi-circular incision, with its convexity in the direction of the coccyx and extending just beyond it, was made from a point about one inch in front of the anterior limit of the anus and on a line, externally, with the tuberosity of the ischium on one side to a similar point on the opposite side. The flap thus made was turned down. The fatty tissue was dissected away, so as to expose the lower end of the rectum and the edges of the glutei muscles. A ribbon-shaped piece of muscular tissue, about one-fourth of an inch in breadth and one-sixteenth of an inch in thickness, was now dissected on each side from the glutei muscles, leaving an attachment above. These two muscular ribbons were transposed, so that the fibers would decussate from one side to the other; in other words, the right-hand muscle was crossed over to the left, the left to the right, underneath the ligamentous connection between the anus and coccyx. These two muscular strips were made to encircle the gut and to meet anteriorly, and were fastened by chromicized catgut. There existed a very small remnant of sphincter muscle on each side of the rectum, and to that the new muscular strips were attached by additional sutures. The finger in the rectum now recognized the constriction formed by this purse-string arrangement, and the flap dissected away was sutured back again in place.

On account of the number of operations already performed in the same region, the superficial tissues were in bad condition, and there was some sloughing of the integument, but distant from the anus.

The operation proved to be a success, as the patient, upon leaving the hospital a few weeks later, was able to satisfactorily retain the fæces, unless the accumulation was liquid, when some leakage occurred; but later on, the newly-made sphincter exercised sufficient control on the bowel to retain its contents under all conditions.

109 E. THIRTY-FOURTH STREET, NEW YORK.

UNNECESSARY ANTISEPTIC TREATMENT IN MIDWIFERY.

By VALENTINE BROWNE, M.D.,
YONKERS, N. Y.
MEMBER OF THE WESTCHESTER COUNTY MEDICAL SOCIETY AND THE JENKINS' MEDICAL SOCIETY; CONSULTING PHYSICIAN AT ST. JOSEPH'S HOSPITAL, YONKERS; PHYSICIAN TO THE ACADEMY OF MOUNT SAINT VINCENT AND TO ST. JOSEPH'S SEMINARY, DUNWOODIE, ETC.

PREVIOUS to the introduction of the antiseptic treatment of wounds by the immortal Lister, antiseptic methods were unknown and consequently unemployed in the lying-in room, nor yet was there any suspicion of the actual presence of those crawling microbes there.

It seems the master minds of such men as Marshale, Hall, Churchill, Meigs, Madam, Lachapele, Velpeau, Burns, Cazeaux, Campbell, Depaul, Smith, and others, never suspected the existence of those prolific and deadly parasites in the cavity of the uterus. From the birth of the first-born of our mother Eve, up to the discovery of the invisible microbes, those destructive enemies of the human race were permitted to freely inflict irreparable injury on our predecessors. If the presence of those invisible parasites had been discovered by Æsculapius, or his immediate followers in the divine art of healing, the actual population of this planet would be so numerous as to almost defy enumeration; even now the human family is pretty large. That the advent and intelligent employment of antiseptic medicine in the practice of surgery has had, and is having, a salutary effect in saving human life there is no doubt, but that the adoption and application of these antiseptic rules in the lying-in chamber has had corresponding beneficial result, I am very much inclined to doubt. In my perhaps limited experience during the past tweny-six years I have personally attended twenty-two hundred and four cases of childbirth. Being somewhat conservative in my notions, I did not adopt the new treatment in my obstetric practice until several years after the introduction of antiseptic medicine, partly for the reason that I had been almost invariably successful in my midwifery practice, and partly because I did not consider the new method had been proved to my satisfaction, and consequently I preferred to follow the rules recommended by the best writers on the subject up to 1876. The glowing accounts, however, that were spread broadcast in nearly every medical publication on the subject of the almost certainty of not only curing all cases of puerperal fever, but also of preventing it, induced me at last, in 1888, to adopt the antiseptic treatment.

Accordingly, when my next case of septic fever occurred I directed the nurse to inject a one-to-sixty solution of carbolic acid into the vagina, with instructions to repeat every two hours until the temperature dropped to 100°F. At my visit the next morning I found the patient suffering from a moderate hemorrhage, temperature 103° F., pulse 120. I then made a careful examination of the vagina and adjacent parts and located the hemorrhage in the cavity of the uterus. Fearing that minute particles of the placenta might be retained in the womb, I injected by means of a fountain syringe a 1-to-2,000 solution of bichloride of mercury into the uterus, which had the effect of checking the flow, but the fever continued to advance notwithstanding the fact that a douche of the before-named solution was administered every second hour, and the best known antipyretics employed. In consultation with the late Dr. N. G. Husted it was decided to discontinue the douche as the condition of the patient was considered hopeless. She died on the fifth day of the fever and the seventh after parturition.

My second case was that of Mrs. C., with her first child; there was a face presentation, instruments were employed, there was ruptured perineum, and fever commenced on the second day after delivery. Morning temperature 102° F.; evening temperature, 105° F.; pulse 140; bichloride douche every second hour, alcohol baths every two hours, patient grew worse and died on the sixth day of the fever.

Case III.—Mrs. E., aged twenty-eight years, developed septic fever on the third day after labor, brisk postpartum hemorrhage occurred due to retained particles of placenta. Antiseptic treatment, and patient grew worse. Dr. Moffatt was called in consultation, when it was decided to curette the uterus and a carbolic douche was ordered four times daily. The patient made a very slow recovery.

In the treatment of these three cases I strictly followed the antiseptic methods recommended by the new school, such, for example, as washing my hands in a 1-to-5,000 solution of bichloride of mercury before making an examination, sprayed my clothing and hair with a still stronger solution of the bichloride, had the vulva carefully washed, and, on account of the labor being prolonged, I had napkins wrung out of the said solution placed over the vulva every hour, and had the instruments placed in a 1-to-20 solution of carbolic acid. After the delivery the vagina was washed out with the bichloride solution, and, in short, I observed and applied every one of what I now consider the absurd and unnecessary antiseptic remedies advocated by the new school of midwifery, with the unsatisfactory results above stated. So much for the vaunted antiseptic treatment in my hands.

I will endeavor to make a brief analysis of the antiseptic treatment now in vogue and perhaps prove the utter impracticability of enforcing its provisions. In the first place it must be admitted that very many of the writers of medical books and articles published in medical journals are eminently theoretical and lamentably deficient in the matter of practical experience. For example, they say that the physician should visit the parturient woman once in each week during the last three months of pregnancy, procure a sample of her urine for chemical and microscopical examination, etc. Every physician having much practical knowledge in obstetrics in a mixed community must admit that it is utterly impossible to fulfill this condition. Is it not a fact that in many cases the physician is not called until within a few days of the event, and often not until within a few hours of labor? Again the average fee paid for confinement in the homes of the toiling class does not exceed $10.00. How, then, in the name of Æsculapius, can the busy doctor make a chemical and microscopical examination of the urine every week and attend his general practice? Is it also not a fact that the physician reaches the bedside just at or about the moment the child is being born and consequently when his attention is urgently demanded must he wait to make an antiseptic solution to wash his hands before attending the patient?

The vagina, say our up-to-date friends, should be thoroughly washed out with the antiseptic solution after the child is born and after an abortion, forgetting the fact that childbearing and the discharge usually following the birth of the child is a perfectly natural or physiological phenomenon and should not be tampered with except in case of the presence of some abnormal condition demanding artificial aid. If it is necessary to flush out the cavity of the vagina after parturition, why not extend the same treatment to the rectum after each stool and to women generally after each menstruation?

Not long since I attended a woman in confinement, and after her rapid and complete recovery she remarked that I did not employ the douche, and that she was very glad to be spared the annoyance. I told her that I never resorted to the douche except in case of some abnormal condition which did not occur in her case. "Well," she replied, "you physicians differ in your treatment; the doctor who attended me at my last confinement directed the nurse to douche me every hour day and night for four days, until at last I became so exhausted that my husband refused to allow any more." "I presume you had septic fever," I remarked. "No, no," she replied, "I did not, but the doctor said that I was threatened with fever and this douche would prevent it and hasten my recovery, yet I was three weeks in bed, and even then I felt weak and very much provoked at the treatment I received and determined to change doctors." This is only one of many such cases brought to my notice during the past ten years.

The furniture in the lying-in room, say our antiseptic friends, should be regulated so as to prohibit the lodgment of disease-producing germs, and the patient should be thoroughly washed from head to foot with a solution of the before-mentioned bichloride before parturition. Now picture to yourself the apartment of a mechanic or a laboring man—and these are the sources whence the vast majority of confinements come—occupying premises embracing the necessary requisites for complying with these conditions.

Again, is it not a fact that this class of patients cannot afford the luxury of a trained nurse, and that they are forced by circumstances to depend on the kindness of neighbors for such nursing as these kind-hearted persons may render them during their confinement? Yet, strange to say, the percentage of recovery is much greater in this same class of patients than in those treated in accordance with the antiseptic method and trained nursing, etc., outside of lying-in hospitals. While it is possible to observe and practise those antiseptic rules in the homes of the opulent and in hospitals, nearly every practical physician will admit the utter impossibility of enforcing those antiseptic regulations in the vast majority of cases in general practice.

Reports from some of the lying-in hospitals, it is true, tell us that the introduction of and application of antiseptic medication had been the means of reducing the mortality from septic or puerperal fever from in some hospitals, 50 per cent. to one-half of 1 per cent. If those rose-colored reports are reliable and the results claimed correct, the antiseptic treatment has indeed, been almost miraculous in the hands of its advocates. I for one beg to question the veracity of those reports, believing as I do that very much of the reduced mortality from septic fever was and is due to other causes than antiseptics, namely, asepsis and hygiene. The old germ-incubators called hospitals have been replaced by new, well ventilated, better located and lighted ones. The disease-breeding cesspool and improper drainage are replaced by an almost perfect drainage system. The filthy condition of the wards and other surroundings have been replaced by cleanliness and a more intelligent application of the rules of hygiene. To these and similar sanitary measures, rather than to the use of bichloride of mercury and carbolic acid, we owe the reduction of mortality in lying-in hospitals.

The advocates of bichloride of mercury in midwifery seem to lose sight of the fact that this salt in even one part to five thousand may act as a poison in the following manner: "After labor the capacity of the vagina is much increased, and when the perineum is *not* ruptured and the patient is lying upon her back when the douche is administered, a portion may for a time be retained in the cavity, the bichloride passing by osmosis into the general circulation." An equally dangerous condition may result from a long-continued use of carbolic acid.

In thus advocating more conservative methods in the treatment of parturition and less meddling with the natural functions of the lying-in patient, I am speaking from practical experience and not from mere theoretical knowledge. I am also aware of the fact that the experience of any one physician, unsupported by the evidence of many others, cannot be admitted as proving the case under consideration.

Previous to and subsequent to the three cases before described, I had in my midwifery practice only three other patients with septic or lying-in fever, one of whom died and two recovered. It will thus be observed that in an experience extending over a period of twenty-six years, during which I personally attended 2,200 cases of childbirth, I had six cases of puerperal fever—three of them were treated in strict conformity with the antiseptic fad, two died and one recovered; three were treated without antiseptics, one died and two recovered.

In other words, I had a mortality of one-half of one per cent. with antiseptic treatment, while the mortality without antiseptic medication was only one-sixteenth of one per cent. Now, if the most ardent advocate of antiseptic treatment in midwifery can show better results, I would like to make his acquaintance. I do not wish to be understood as being anxious to claim any special or unusual knowledge in the treatment of this class of patients. My custom has been and is now to exercise what common sense I can command, and by insisting on absolute cleanliness, a plentiful supply of fresh atmospheric air night and day, and the free use of sterilized water, never resorting to the douche except in cases where the discharge from the vagina becomes fetid—then sterilized water was used. Instruments, when I had occasion to use them, which occurred sixty-four times, were washed in boiled water before and after using, and a portion of boiled water, with the addition of one teaspoonful of table salt to each quart was used in cleansing ruptured perinei.

From these facts I have naturally concluded that antiseptic treatment as recommended in midwifery by many of the modern text-books is not only unnecessary, but also is not wholly free from danger to the patient.

In looking over one of our medical journals the other day, I observed the following verses, which I consider very amusing and appropriate here:

We have boiled the hydrant water;
  We have sterilized the milk;
We have strained the crawling microbes
  Through the finest kind of silk.
We have bought, and we have borrowed,
  Every patent health device,
And at last the doctors tell us
  That we've got to boil the ice.

Now, to sum up, as our legal friends say, I have attended the number of confinements before stated, had six cases of septic fever and three deaths; five cases of puerperal convulsion and one death; three cases of face presentation, and one death of child; six cases of placenta prævia, and no death; ten cases of abortion, all mothers recovering; sixty-four cases of instrumental delivery, and no deaths; five cases of shoulder presentation, and no deaths; fifteen breech presentations, no deaths. There were many other abnormal presentations, a description of which would perhaps be tedious. Permit me to add, however, that I had twenty-six cases of ruptured perineum, all of which, with only one exception, rapidly healed. Only once in my experience did I find it necessary to perform craniotomy, and then only when Dr. Benedict and I decided that the child was positively dead. One of my cases of puerperal convulsion was caused by a very short cord (five inches) and *no* placenta—a fact which an examination of the womb disclosed, a living child being removed from its dead mother by Cæsarian operation. I might also state that I had one dead-born child in every 400 births.

In conclusion, permit me to mention briefly the use of ergot in the hands of the accoucheur. This medicine has long been credited with the power of stimulating uterine contractions during labor, and a potent remedy in inertia of the uterus. Of late years, however, the use of ergot is by most recent writers considered dangerous to the life of the child and of causing continued and unnecessary pain to the mother. My experience with the drug does not confirm this theory. I have employed ergot in every case of inertia of the uterus, and always with complete success. I would say, however, that I never administered this potent remedy except in the following conditions: When from any cause the labor pains become very feeble and the os uteri was completely dilated, or when it was soft and petulant and the membranes were ruptured, and when the pelvic outlet was normal and the patient had previously borne children. When these conditions were present it has been my treatment to administer drachm doses of a reliable fluid extract of ergot, and if labor should not terminate in half an hour, I repeat the dose, and always with the most gratifying result.

On the Anæmias Called "Splenic Anæmia."—S. Vere Pearson holds that there are no such definite pathological changes discoverable as a foundation to earn for these anæmias their recognition as a distinct disease. Nor are these changes even sufficiently definite to justify their being grouped together under one name. As long as the physician is content to make the diagnosis of "splenic anæmia," so long will the full investigation and sorting out of these cases remain at a standstill. A more definite and scientific basis for classification must be sought for than that founded upon a mere association of symptoms. Finally, as far as our present knowledge on these matters enables us to come to a conclusion, it seems best to consider the anæmias, at present grouped under the name "splenic anæmia," as varieties of secondary anæmia associated, by causes as yet undetermined, with enlargement of the spleen.—*The Medical Chronicle.*

WHAT CAN WE DIAGNOSTICATE IN ACUTE APPENDICITIS?*

BY CHARLES A. ELSBERG, M.D.,
ADJUNCT ATTENDING SURGEON TO THE MOUNT SINAI HOSPITAL, NEW YORK.

Whenever the subject of acute appendicitis comes up for discussion in any of our medical societies, most attention is generally given to the consideration of the indications for operation and the time when operative interference is advisable. The question usually discussed is: "When shall we operate in acute appendicitis?"—in other words, what symptoms call for immediate surgical interference in this disease? In the present state of our knowledge it is recognized that we cannot make the diagnosis of the pathological condition of the appendix and therefrom deduce principles of surgical treatment. In this country most surgeons are agreed that the early operation is, in many cases, the safest, and that an appendix which has once been the seat of disease had best be removed. The extreme conservatism of the French and German surgeons is slowly yielding to the radical ideas of operators in our own country, such well-known surgeons as Rehn, Tuffier, and Czerny being recent converts to the doctrine of early operation.

Unfortunately, we have not, and may never have, at our disposal pathognomonic signs which will enable us to say in each case whether the appendix vermiformis is the seat of mild or of severe lesions. Hence it is safer to remove the organ in most acute conditions, and we have to content ourselves with finding the indications for the time when such operation is to be done in the character and frequency of the pulse, the temperature, the degree and extent of the pain, and the conditions found on physical examination. The character and frequency of the pulse are of foremost importance as indications of the degree to which the general system is affected by the disease, and therefore, in a limited sense, of the severity of the inflammatory process; the height of the temperature has its value, as it often shows to us the reactive powers of the organism; the severity and area of distribution of the pain have their value, as have a number of other signs and symptoms. Experience has shown, however, that none of these signs are characteristic of one or other lesion of the appendix. The mildest symptoms may go hand in hand with the gravest lesions, and the severest symptoms are often caused by relatively slight pathological changes in the appendix.

The physician, and more especially the surgeon, should not, however, be deterred from the attempt to formulate in his own mind the condition of the organ which he is to remove at an operation. I do not believe that any confusion will result from asking ourselves the two questions: When shall we operate, and what can we diagnosticate in acute appendicitis? Further advances in our clinical knowledge of this affection can only be made along these lines of investigation.

In this paper I shall attempt to answer, to some extent, the second of these questions: In the present state of our knowledge of acute appendicitis, what pathological conditions can we recognize from the signs and symptoms presented? I shall consider the subject under the following headings:

1. Can we diagnosticate the position of the appendix?

2. To what extent can we diagnosticate the changes that have occurred in and around the organ?

3. What can we determine regarding the general peritoneal cavity?

4. Conclusions.

1. *Can we diagnosticate the position of the appendix? Does it lie behind, in front of, external to, internal to, or below the cæcum?*

In many ways this is a point of importance. In the first place, a knowledge of the exact position of the appendix is of great value to the operator. If he knows the exact location of the organ he can approach and expose it in the best and quickest manner, and in many cases he will be able to make his incision smaller than otherwise. Every surgeon knows how difficult it may be to find the organ. If he feels fairly certain where to look for the appendix before he begins the operation,—no matter whether it lies in a mass of adhesions or somewhere in an abscess cavity—his operative work may be rendered much more easy. In the second place, a knowledge of the position of the diseased organ may influence our prognosis, and therefore make the indications for operation more or less urgent. In adults, when the inflamed appendix lies behind the cæcum, firm adhesions are formed early, and the cases are more apt to run a favorable course than in children. This is, perhaps, due to the close proximity in children of the liver and the great absorbing lymphatics of the right side of the diaphragm (Recklinghausen). The inflamed appendix situated below the cæcum is more apt to be complicated by an abscess in the pouch of Douglas, the appendix internal to the colon, by early invasion of the general peritoneal cavity.

Medical literature contains few references to this subject. The situation of a tumor, if present, in the right iliac fossa or in the pouch of Douglas, the location of the greatest tenderness to pressure, and a number of other physical signs, may, in a general way, indicate where the appendix is to be found. Excluding those cases, however, where the diseased organ can be made out on palpation, we have seldom been able to determine the exact position of the appendix before operation. Some writers have claimed that the diseased organ generally lies beneath the point where there is the greatest tenderness. I have examined a considerable number of patients for this point of great tenderness to pressure, and in many cases the diseased organ was found at some distance from this point. I have endeavored in seventy cases of acute appendicitis to localize the organ by the following simple method, and at operation I found that the appendix had been correctly localized in sixty of the patients.*

The appendix is considered to lie between two points, one the apex of the cæcum, the other the diseased portion of the organ. The apex of the cæcum corresponds in general to what is known as McBurney's point. In children this point, which is taken only as the anatomical base of the appendix, lies one to two c.m. above where it would lie in the adult. The second point on the abdominal wall is the one at which the patient localizes the greatest subjective pain, and it is to be found in the following manner. Ask the patient to point with one finger to the spot where he has the most pain, without looking at his abdomen, and as quickly as possible. Make him repeat this procedure a number of times until you are certain that the correct point has been obtained. Then the general course of the appendix will lie between the base of the organ and this point. The appendix may be bent upon itself, and then run in some other direction; it may run beyond the second point, but a considerable portion of the organ will be found between these two points. Very early in the disease this method cannot be made use of, because the first pain complained of is generally around the umbilicus. The organ will be wrongly located in cases where there is a congenital absence of the ascending colon, but these are only exceptional. Where there is already well-marked general peritonitis, the patients are generally unable to say where they have the most pain. Among the seventy cases that I have examined there were ten in which the organ could not be, or was wrongly, located. Two were cases of short or absent ascending colon; three were in patients who were unable to say where they had the most pain; in the five remaining cases there was diffuse peritonitis, so that the patients complained of much pain in all parts of the abdomen.

---

*Read at the meeting of the Metropolitan Medical Society, January 28, 1902.

*The greater number of these cases occurred on the surgical service of Dr. Howard Lilienthal at Mt. Sinai Hospital.

2. *To what extent can we diagnosticate the changes that have taken place in the appendix and its immediate surroundings?*

These cases may be divided into (*a*) Those in which no mass is to be felt; (*b*) Those in which a mass is to be felt.

(*a*) *No mass to be felt.*—Most authorities are agreed that we can seldom feel the normal appendix, and that an appendix that has once been the seat of an inflammatory process and can be felt must not be called a normal appendix. If the symptoms of appendicitis are mild—the temperature not high, the pulse below 100 beats to the minute (except in children and in nervous individuals), the abdomen soft, with little or no rigidity of the right rectus muscle, no mass to be felt, the tenderness only very slight and of only one or two days' standing—the appendix is probably the seat of slight changes. In these cases, however, especially if there is a history of one or more previous attacks, the wall of the organ may be so much diseased that a localized ulceration, perforation, or gangrene can occur at any moment, and a rapid absorption of toxic material or acute infection of the peritoneal cavity follow. Therefore, even the mildest attacks require careful watching. Any moment the clinical picture may change, the pulse and temperature rise, the pain become more severe and spread, and immediate operation become indicated.

It is generally impossible to diagnosticate correctly a perforation or gangrene of the appendix in a case where no mass is to be felt. A sudden collapse or the sudden onset of very severe symptoms during the course of a mild attack often indicates a perforation as the cause. Physical examination may reveal nothing but the sudden appearance of extreme rigidity of the right rectus muscle, perhaps accompanied by a chill or a sudden increase of the pulse rate. A localized gangrene may sometimes be suspected where the general symptoms are of short duration, but are altogether out of proportion to the local signs.

(*b*) *A mass is to be felt.*—The diseased appendix can sometimes be recognized on palpation when it is much thickened or distended with fluid, and when there is little or no rigidity of the right rectus muscle. A mass in the right iliac region in appendicitis generally means that the inflammatory process has extended beyond the appendix; *i. e.* there is a localized peritonitis in the right iliac fossa. Either there is an abscess or a mass of adhesions around the diseased organ. If the mass is of soft consistency, with tympanitic resonance over it, it is probably a mass of adherent intestine, perhaps with a small abscess in its center. Large abscesses, and often small ones, may be recognized by the characteristic feel and their immobility. Aside from the height of the temperature and the pulse, etc., one can often say from the characteristic feel of the mass that there is an abscess. In a certain number of cases there is a small mass which is freely movable from side to side. Such a freely movable mass is generally the inflamed appendix with some omentum wrapped around it. A thrombosed mesentery of the appendix may sometimes be suspected where the attack of appendicitis is only of one or two days' duration, but where the patient has had frequent severe chills during the course of the disease, and where malarial poisoning can be excluded.

An exudate which persists longer than two to three days without diminishing in size, or is increasing in size, always contains pus as its nucleus. It may be that the pus is small in amount, or that it is well encapsulated and not under great tension. In such a case the symptoms may be mild, and may remain so for days, weeks, or months. I recently operated upon a patient whom I had seen about two months before with a large, tender mass in the right iliac region without a single symptom excepting localized pain. Although warned of the danger, he walked around for two months withholding his assent to the operation. He finally concluded to be operated upon, again consulted me, and was prepared for immediate operation, at which I opened a large abscess, which contained much foul pus. During the two months the size of the tumor had remained unchanged, and the pain had remained the same. If the pus is under great tension and not well walled off from the general peritoneal cavity, the symptoms will become progressively more severe. Sudden disappearance of the mass means rupture into the general peritoneal cavity or into a hollow viscus, and is accompanied by an evanescent or permanent amelioration of the symptoms, perhaps with a discharge of pus by rectum or urethra.

When, in appendicitis, a mass is to be felt by rectal examination it means an inflamed appendix partially in the pelvis, or a secondary abscess or adhesions in the pouch of Douglas, or a gravitation of fluid from the general peritoneal cavity into the pelvis. The tip of the inflamed organ can sometimes be felt by rectum, and is then an aid in the diagnosis of the location of the diseased organ.

Periappendicular abscesses are most often caused by perforation or gangrene of part or of the entire organ, but in a certain number of cases an abscess is found around an appendix which is only slightly diseased. In the patients, therefore, who give a history of acute appendicitis, and who have a mass in the right iliac fossa, we can only diagnosticate "acute appendicitis-abscess;" we can never say beforehand what pathological changes have occurred in the appendix.

3. *What can we diagnosticate regarding the general peritoneal cavity?*

If all the classical signs and symptoms of general peritonitis are present—and I need not enumerate them—the diagnosis can always be made with ease. Can we, however, make a diagnosis that the peritoneal cavity is in immediate danger, or that infection or inflammation has already begun? Slight general tenderness and tympanites have little more than confirmatory value; they are often present, especially in children or nervous individuals, where the general peritoneal cavity is found normal at the operation. Spreading pain and tenderness in the abdomen have their value, especially in advanced cases, as have tympanites, obliteration of the liver, dulness, dulness on percussion in both lumbar regions, repeated vomiting, constipation, and the general symptoms relative to the pulse, temperature, and the general appearance of the patient. Rigidity of the abdominal muscles, and especially of the left rectus muscle, in addition to that of the right side, is often of the greatest value. It is a rigidity that does not disappear when the patient is under the influence of narcotics, and not until he is under deep anæsthesia. This rigidity is often present before the pulse has begun to rise. I have operated upon four cases during the past year (two in adults and two in children) where the symptoms were mild, the pulse slow, the temperature not high, where the main indication for immediate operation lay in the extreme rigidity of the abdominal muscles. In all four cases the general peritoneal cavity contained turbid fluid; in two the gangrenous appendix was found free in the general peritoneal cavity, in the other two cases it was only partially walled off by adhesions.

In the attempt to arrive at a conclusion regarding the condition of the general peritoneal cavity, every one of the signs must be carefully weighed. Even in the absence of a rise in the pulse-rate or a sudden extension of the pain or tenderness, I have learned to look more and more upon marked abdominal rigidity as an indication of impending trouble in the peritoneal cavity.

The differential diagnosis between acute appendicitis and other affections is generally easy. Occasionally an affection of the gall-bladder, a torsion of the omentum, a new growth in the intestine, an intestinal obstruction, an affection of the female adnexa, or a reflected pain from thoracic disease may make differentiation difficult.

The frequency of appendicitis must be kept in mind. It is more frequent in the late spring and the summer months, and more severe cases occur in large cities, probably from hygienic and dietetic causes. On the service of Dr. Lilienthal at the Mt. Sinai Hospital during 1900, 77 per cent. of the cases of right-sided abdominal disease, and 68 per cent. of all abdominal affections, exclusive of hernia and affections of the kidney, were due to inflammation of the appendix vermiformis.

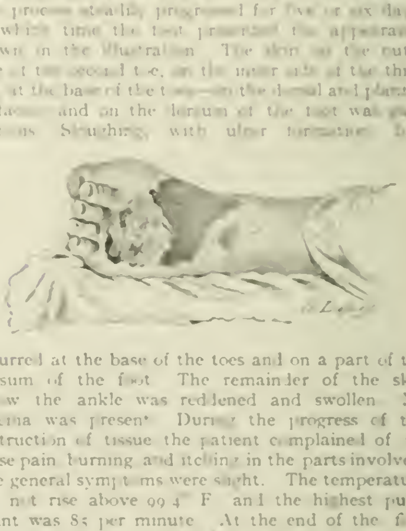
In the foregoing remarks but a few points have been considered, and these from a standpoint that might be called narrow. It would be just criticism to declare that for a disease of such a protean character as is acute appendicitis one cannot lay down any fixed rules, one cannot make any fine pathological distinctions between the various forms of the disease. As has already been said, in some cases the severity of the disease is in inverse proportion to the severity of the symptoms. In other cases the changes in the appendix remain slight, but the symptoms of general poisoning are very severe. Most operators must have seen deaths from general septicæmia in cases where the appendix was only moderately diseased. Up to the present time, therefore, we are able to recognize few of the pathological changes that have occurred in the appendix. We must still depend upon the pulse, the pain, the temperature, and the other symptoms as indications of the severity of the disease and of the treatment to be followed. It would be a manifest error to attempt to diagnosticate the pathological condition of the appendix, and to find in the pathological diagnosis the indications for or against operation. Such a course would most certainly be followed by the direst results. We must find our indications for operation in the condition of the pulse, the pain, the temperature, the general symptoms, and the results of the physical examination. We may, however, learn more of this disease by attempting to have a better pathological knowledge underlie our principles of operative treatment. It is with this object in view that the subject has been approached in this paper from what I venture to call a somewhat novel standpoint.

Clinical Department.

CARBOLIC ACID GANGRENE, WITH REPORT OF A SEVERE CASE.

By JOHN GLENDON SHELDON, M.D.,
[illegible]
[illegible]

MARY F., age twenty-six, servant, unmarried, applied a few drops of a 50-per-cent. solution of carbolic acid to a corn situated on the outer side of the second toe of the left foot. The carbolic acid was dropped on some absorbent cotton which was held on the corn about one-half a minute. The cotton was then removed, the site of application dried with a towel, and the foot washed in water. The tissue brought in contact with the acid appeared white and felt numb, but was not painful. Twelve hours later a burning sensation was felt over the entire foot; the affected toe had reddened and slightly swollen, except the area where the acid had been applied, which was black and felt "dead." The process steadily progressed for five or six days, at which time the foot presented the appearance shown in the illustration. The skin on the outer side of the second toe, on the inner side of the third toe, at the base of the toes, on the dorsal and plantar surfaces, and on the dorsum of the foot was gangrenous. Sloughing, with ulcer formation, had occurred at the base of the toes and on a part of the dorsum of the foot. The remainder of the skin below the ankle was reddened and swollen. No œdema was present. During the progress of the destruction of tissue the patient complained of intense pain, burning and itching in the parts involved. The general symptoms were slight. The temperature did not rise above 99.4° F., and the highest pulse count was 85 per minute. At the end of the first week the symptoms gradually abated, the dead skin sloughed, the redness of the foot disappeared, and evidences of resolution could be noted. The healing of the ulcerated areas was slow and resulted in the formation of a considerable amount of scar tissue.



The treatment consisted in keeping the foot clean. During the progressive stage of the process a dilute solution of cocaine was occasionally applied to the foot to relieve the pain. Two hypodermic injections of morphine were given for the same purpose. When resolution began, zinc-oxide ointment and Lassar's paste were used locally.

The physical examination, uranalysis, personal history, and family history of the patient were entirely negative, excepting the following facts. Two years ago the patient and her sister accidentally got some carbolic-acid solution—strength not known—on their fingers. A condition similar to the one described above that occurred in the patient's foot affected two fingers of the patient and a finger and thumb of her sister. The affection of the fingers resembled that of the foot, being characterized by pain, burning, itching, and redness with gangrene of the skin, followed by sloughing and resolution.

The case herewith reported illustrates two points concerning carbolic-acid gangrene that are worthy of separate consideration. I refer to (1) The importance of the idiosyncrasy of the patient regarding etiology; and (2) The extension of the gangrene beyond the borders of the area brought in contact with the acid.

In the Medical Record of November 16, 1901 ("Gangrene Following the Use of Carbolic Acid"), I made the following statement: "The explanation of the occurrence of carbolic-acid gangrene cannot at present be satisfactorily given. It is not known why gangrene should occur in one case, and no injury to tissue take place in another individual treated in an identical manner. It is probable that the idiosyncrasy of the patient and the surrounding conditions play an important part in each case." The case herewith reported illustrates personal and family idiosyncrasy; the patient does not know that she has ever been exposed to the action of carbolic acid excepting twice (mentioned in the foregoing report), and in each instance gangrene resulted. The patient's sister's experience with carbolic acid has already been mentioned. Fischer (*Münchener medicinische Wochenschrift*, August 6, 1901) reports two cases of gangrene following the local application of carbolic acid to slight injuries. The patients were brothers, and Fischer assumes a family idiosyncrasy for the drug. Fischer's cases and those that I have reported indicate that idiosyncrasy plays a more important part in the etiology of carbolic-acid gangrene than has heretofore been assigned to it in discussions of this subject.

It has generally been believed that gangrene resulting from the local use of carbolic acid limits itself to the area brought in contact with the drug. I have been unable to find any positive statement on this subject, except that made by Levi, who says that the gangrene is limited to the area to which the carbolic acid is applied. In the Medical Record, November 16, 1901, I reported a case of gangrene—supposed to have been caused by the local use of carbolic acid—that began in the foot and rapidly extended to the middle of the thigh. This case and the one herewith reported are the only cases of spreading carbolic-acid gangrene that I have seen recorded.

TETANUS; RECOVERY AFTER THIRTY-SIX DAYS.

By J. BURTON NOWLIN, M.D.,
BUCKINGHAM, VA.

On November 27 Thomas G——, a saw-mill hand, fell on an axe, cutting his right hand on the ulnar side. The cut was an inch long on the palmar and an inch and a half on the posterior surface, extending to the bone. When he came to have it sewed up the same afternoon he had done nothing except pour spirits of turpentine into it, and tie up tightly to stop the hemorrhage. I dressed and sewed it up. Ten days later he came to have the stitches removed. The wound had healed by first intention. There was a minute stitch abscess on the back. The following Wednesday he sent me a message to come, his jaws being clinched and he could not open them. On reaching there I found him as he had said. On being questioned, he managed to tell me that on the Sunday before, ten days after the accident, he had felt some stiffness in his jaws, and thought it due to cold, but it had grown steadily worse. His teeth were firmly clinched, his head drawn back, the sternomastoids rigid; there was the risus sardonicus; great beads of sweat stood on his forehead. His pulse was 120, and full; temperature 101° in the axilla. The tonic spasms came on every fifteen minutes, affecting at this time only the body, arm, and neck muscles. The abdomen was rigid. There was very little difficulty in swallowing. Perspiration was slightly quickened. The clonic spasm was complete as far as the arm, neck, and belly muscles were concerned. He talked in a sharp, explosive manner. His mind was clear, and continued so throughout the disease. He was not sensitive to noise or light at first, but gradually became so after a few days, and complained of the light giving him pain, but neither light nor noise seemed to have influence on the spasm. He was constipated from the first.

Having no chloral with me, I left some morphine and atropine tablets, to be given often enough to keep him quiet. Retention of urine followed this, so I stopped it and put the patient on chloral. The dose at the beginning was 15 grs. every four hours, gradually increased until he was taking 20 grs every three hours. This did not keep him from having the spasms entirely, but nearly so. About the tenth day his legs became involved. He complained of the pain at this time being altogether from his waist down, and it seemed to be excruciating. The tonic spasms were more pronounced, his body being arched, resting on his head and heels. Every muscle stood out prominently. At this time I began the use of carbolic acid. One grain of the crystalline dissolved in four syringefuls of tepid water was inserted in four injections. The injections were made deep into the muscular tissue. This dose was afterwards increased to a grain and a half in the same quantity of water. He complained of a slight burning afterwards, but not enough to bother him. The muscles injected became almost immediately softer and more pliant. The effect lasted for about an hour and a half. I was able to give him but one injection daily. These injections were kept up for fifteen days, when the clonic spasms had nearly relaxed, and the insertion of the needle caused a great deal of pain and made the tonic spasms more severe. At this time he would have only five or six jerks in twenty-four hours. He had an insatiable appetite, and kept some one constantly fixing something he could eat. He could now open his jaws about an inch and a half. The longitudinal fibers of his tongue were in a spasmodic state, so that he could only get it to his teeth. The constipation was relieved by large doses of Epsom salts at first, and by saline enemata later on. The chloral was reduced slightly from time to time, and six weeks from the beginning of the disease he was discharged. From a strong, robust laborer he was reduced to a mere skeleton, as weak as a baby, and complained of great aching and soreness through his muscles, particularly his legs.

REPORT OF A CASE OF FOREIGN BODY IN THE TRACHEA.

By WALTER W. STEBBINS, M.D.,
MOUNT VERNON, WIS.

About the middle of January, I was hurriedly summoned to see a boy, one year old, who had eight successive attacks of violent paroxysms of coughing, with marked asphyxia, ending in unconsciousness. The first attack came on suddenly while the child was playing upon the floor with an ear of corn, from which he had detached a great number of the kernels. The succeeding paroxysms occurred at intervals of from fifteen to thirty minutes.

A hasty examination with the stethescope confirmed the suspicion of foreign body in the trachea. The sound heard when the stethescope was placed over the trachea in the neck was very peculiar and distinctive. The kernel of corn could be heard rattling up and down in the trachea with each respiration, and with each expiration it would impinge against the vocal cords with a sharp click, producing a crowing sound such as is often heard in cases of croup.

I immediately inverted the little fellow and gave him several sharp slaps on the back between the shoulders. The immediate result was alarming, for respiration ceased at once and unconsciousness supervened. I placed him upon the floor and after five minutes of artificial respiration, consciousness was restored. I then tried the effect of emetics. The result was disappointing, for although I gave them in good-sized doses, the vomiting produced was of a passive type and not of the violent expulsive nature I had hoped to excite; moreover, following each paroxysm of vomiting respiration would cease and unconsciousness supervene, necessitating artificial respiration.

As the little fellow was growing rapidly weaker and the paroxysms more severe and of longer duration, I deemed it unwise to longer delay tracheotomy. This I, accordingly, performed, ninety minutes after first seeing the patient, during one of the periods of unconsciousness, with the patient lying upon the floor in the midst of the many kernels of corn he had removed from the ear. Wearing apparel and the contents of my emergency bag were scattered about in the greatest imaginable confusion. Asepsis was out of the question, and the only assistant available was the mother of the patient, she being the only other person in the house besides myself (except the three-year-old daughter, who added to the general confusion by continually crying). It was necessary to suspend the operation three times to perform artificial respiration. On opening the trachea and separating the edges of the wound, the kernel of corn popped out during an attempt at expiration.

Not having the proper sutures at hand, I left the wound open, and during the next few days the little fellow coughed much mucus through it, he having had a bronchial catarrh for several weeks. By the eighth day the mucous had ceased to appear through the opening, and by the fourteenth day granulation was complete, and the wound healed, recovery being prompt and uneventful.

Such of my professional brethren who read this report and who have similar cases, I trust will profit by two mistakes which, I am convinced, I made in the conduct of this case, namely, attempts to recover the foreign body by either of the two methods which naturally suggest themselves to one first—inversion and the administration of emetics. These measures cause the foreign body to impinge upon the vocal cords, producing spasm of those organs and the glottis. The resulting symptoms are alarming. I should advocate immediate operation in these cases, before the strength of the patient is exhausted.

ARE SEEDS POTENT FACTORS IN THE PRODUCTION OF DISEASE OF THE VERMIFORM APPENDIX?

By JAMES C. KENNEDY, M.D.,
SURGEON TO ST. CATHARINE'S AND ST. MARY'S HOSPITALS,
BROOKLYN, N. Y.

A SHORT time since I removed watermelon seed from the vermiform appendix.

Little interest would attach to this were it not that it is a common belief among the laity and a few medical men that should a seed of any kind be swallowed it would immediately find its way to the vermiform appendix and there set up a serious, if not fatal, inflammation.

The reported experience of surgeons throughout the country in reference to this matter is such as to lead one to believe that a seed seldom, if ever, enters the appendix. While all writers admit the possibility of such occurrence, comparatively few have proved it.

From a careful perusal of works on operative appendicitis by competent men, I find that all make the positive statement that, up to the time of writing, not one had discovered a seed in the vermiform appendix. Hospital and private practice for some years back have given me considerable experience in this disease, and while I am not prepared to state the exact number of cases I have operated upon, this is the first seed I have found in the appendix.

Fixing the number of cases operated on by the three authors above mentioned up to the time they wrote their book at an extremely low figure, say two hundred and fifty cases, and my own at the same number, together with a more or less careful search of medical literature in order that I might be able to estimate approximately, besides a personal inquiry of a number of surgeons of large experience, I venture to place the presence of seeds or foreign bodies in the vermiform appendix at one in a thousand cases.

Chronic Progressive Deafness.—Mayo Collier discusses the form of deafness which occurs insidiously, without pain or discomfort in the ears, and only becomes apparent to the individual when a marked impairment of hearing has taken place. He believes that in the associated conditions of a chronic cold in the head with partial obstruction to nasal respiration there is every factor necessary to produce the condition known as sclerosis of the middle ear. Detailed reasons are given for this belief. Cases taken early can be improved, even cases considered incurable can often be greatly helped. The nose may be quite free, but the septum may have a depression corresponding to the convexity of the lower turbinal body, and on the pharynx there may be patches of atrophy with dilated veins and islets of enlarged gland substance. On trial of the Politzer bag one will probably fail to get air in, but after an antiseptic and astringent wash, perhaps in a week's time, air will enter. The galvanocautery will put a stop to this latent obstruction and relieve the congestion of the nasal and postnasal space by letting in air, and give tone to the vessels. The nose being ventilated and the potency of the Eustachian tube restored, the drum head should be daily exercised by gentle movements imparted by Politzer's bag and Seigle's aspirator. In a large percentage of cases this results in marked and permanent improvement of hearing.—*Medical Press and Circular.*

Albuminuria Considered from the View of Life Insurance.—B. J. Stokvis says that, according to Zechinson and Noosden, the percentage of cases of extra-renal albuminuria is from 60 to 68 per cent. As a mark to distinguish renal from extra-renal albuminuria, the author says that the predominance of nucleo-albumin in the urine is a good proof of extra-renal albuminuria, but the microscope is to be preferred to chemical methods. As to renal albuminuria, there are many cases which are functional, and result from curable diseases of the kidneys. The only absolute signs of an incurable disease of the kidneys are: Kidneys—alteration of diuresis, oftener polyuria and pollakiuria (presence of renal cylinders, etc.), Heart—hypertrophy, dilatation, Arteries—endarteritis (arteriosclerosis); Eyes—hemorrhagic retinitis; Nervous System—uræmic symptoms; Skin—œdema, exanthema. When a rigorous examination fails to disclose one of these symptoms, the existence of an incurable disease of the kidneys is very improbable, notwithstanding the presence of albumin in the urine, and the candidate for insurance should be accepted. When one of the above symptoms is found, when diuresis is increasing, and the specific gravity of the urine is below 1.013-1.010, nephritis undoubtedly exists, notwithstanding the absence of albumin in the urine, and the candidate should be refused.—*The Medical Examiner and Practitioner.*

New York, April 5, 1902.

THE CAUSE OF CARCINOMA.

THE subject of carcinoma is just now attracting an extraordinary amount of attention, but no more than the importance of the subject warrants. We know our limitations in the radical surgery of carcinomatous disease, and we recognize the fact that our best efforts do not cure, but only, in a small proportion of cases, annihilate the neoplasm; but it is the causation and not the removal of cancer which is being studied so energetically at present. In last year's *Transactions of the American Surgical Association*, Park of Buffalo published an important paper bearing upon this subject; and coming from a laboratory whose workers are among the strongest supporters of the theory of the parasitic origin of the disease, the conclusions cannot fail to engage attention. Before commenting specially upon this paper, we may note that practically all pathologists are agreed that carcinoma is the result of perverted epithelial growth, though there is no such agreement as to the cause of such perverse activity. It is hardly necessary to say that many theories have been advanced to explain this, none of which can be called satisfactory from all points of view.

In the Buffalo laboratory a large number of inoculation experiments have been made, and by these and others it is pretty well established that certain elements of the cancerous neoplasm can cause a perversion of the normal activity of the epithelium of the part to which they have been transplanted. The supporters of the parasitic theory believe that they have been able to demonstrate the presence of an organism, the irritating influence of which is responsible for the cellular changes which constitute carcinoma. In judging the results of inoculation experiments, it must be remembered that cellular proliferation will be set up almost invariably by the introduction into the living organism of materials like those used in the experiments, and that this proliferation is not necessarily carcinoma. Carcinoma is proliferation in a particular way.

Because carcinoma is inoculable, it does not follow that there is present a specific organism which is responsible for the tissue change which we call carcinoma. Numbers of experiments like those referred to have been made, which show that carcinoma may be transmitted by transplantation of portions of the growth, or by inoculation with fluids extracted from it, but this does not prove that a living organism is the active agent in the transmission. One point made by Park is that we need not necessarily expect rapid progress in the course of pathological process, due to an infecting organism, since we are familiar with several slow infective processes, and that, therefore, the comparative slowness of the carcinomatous process is not against its being caused by a microorganism. We may admit the force of this without admitting that any support is thereby afforded to the hypothesis that cancer has its causation in a microorganism. So far there has not been enough evidence presented to warrant much faith in the Buffalo idea. Practically, all the evidence offered is that given by certain fairly constant, but somewhat irregular microscopic appearances, which the majority of observers believe to be due to cellular changes and degenerations, but which are said by the supporters of the parasitic idea to be caused by the life processes of a specific microorganism, probably a protozoon. Absolute proof is wanting on both sides, but the weight of evidence is against the parasitic theory, and the *onus probandi* rests with its supporters.

An interesting aspect of this question is opened by considering the possibility of an antitoxine treatment of malignant disease. If the advocates of the parasitic theory were able to bring convincing proof of the correctness of their ideas, it would be entirely reasonable to suppose that there may be developments towards an antitoxin treatment of the disease, and if the disease is definitely shown not to be due to any microorganism, it is still within the bounds of possibility that the same line of treatment would prove successful. We know that the cancer cells, like all cells, require room in which to grow, and suitable nutritional material, and that when they are crowded together there is a tendency towards degeneration in a number of them This degeneration may be due to an accumulation of the products of the metabolism of the cells, which act like antitoxins in a way analogous to what we see in the case of a true microorganism, when culture material becomes too thickly filled with the growth, and it is possible that a more intimate knowledge of the life history of the normal and the abnormal epithelial cell may lead to important developments along this line. The conquest of cancer must apparently rest with the pathologist, but until the latter is ready, the surgeon must remain our chief dependence.

WORD-BLINDNESS.

THE faculty of speech is a complex function, and comprises not only the mechanism of articulation, but also a revival of various sense-memories, representing the great number of impressions received from without. Paralysis of the motor apparatus of articulation, while it prevents speech mechanically, does not necessarily interfere with those processes that underlie the psychic activity whose expression we know as intelligent speech. On the other hand, we may have, without interference with the mere act of articulation, such derangement of receptive or emissive cerebral function as to impair or even to abolish the power of speech. To the latter condition the designation aphasia is applied, and three principal varieties have been distinguished, namely, motor, sensory and amnesic. It is difficult, however, to maintain any such classification, and not rarely the speech-disturbance is complex, although one form may predominate, and all sorts of combi-

[illegible] may take place. Thus, the power of speaking, spontaneously (with or without confusion) or by repetition, or of reading, to oneself (or aloud) with or without comprehension, or of writing spontaneously (with or without confusion) or on dictation or by transcription, or of comprehending the spoken, written or printed word or figure or other symbol may be lost, one or more, in varying degree.

A condition closely related to aphasia is that known as mind-blindness, or object blindness, or as visual or optic aphasia, in which, although the object is seen, the patient is unable to recognize or to designate it. Of this a special variety is known as word-blindness; there may also be a letter-blindness. Four striking examples of word-blindness have been recently reported by Dr. Jas. Hinshelwood (*Lancet*, February 8, 1902, p. 358), who has already made several contributions to this interesting subject. In one of the present cases a man familiar with four languages was found almost totally word-blind to one, less word-blind to two, and not at all word-blind to the fourth. The explanation of this strange phenomenon is thought to reside in the fact that only a portion of the center in the cerebral cortex—probably situated in the supramarginal and angular gyri of the left hemisphere in right-handed persons—in which are lodged the word-visual images of language is destroyed, the cells subserving the function for each language forming separate groups. It has already been observed that a patient familiar with two languages may be word-deaf to one and not to the other, and an analogous explanation is probably applicable also here. In the second and third cases of word-blindness the patient could read printed letters quite well, but written letters with difficulty if at all. There was little interference with the reading of figures in these two cases, as well as in the fourth, in which there was complete word-blindness and also letter-blindness and an inability to designate by name objects seen, although these were apparently recognized. The first patient retained the power of reading musical notes.

In the second and fourth cases there was right lateral homonymous hemianopsia. The frequency with which this association has been noted suggests that the centers for visual memory and for the right halves of both visual fields, or the paths to them, must lie close together, and this inference is confirmed by pathological evidence. The question as to recovery from word-blindness depends upon the nature and the situation of the causative lesion. If this be destructive, recovery is quite out of the question, except in so far as the opposite hemisphere can be educated to take up the lost function. Whenever syphilitic infection is even suspected a vigorous course of mercury and iodid should be instituted.

VICARIOUS ELIMINATION FOLLOWING REMOVAL OF THE KIDNEYS.

The effects of any toxic substance introduced into the body must depend upon the rate with which it is absorbed and eliminated. In the case of strychnine it is believed that such elimination takes place almost wholly through the kidneys, and it has been thought that removal of these organs, or ligation of their vessels, would be attended with an accumulation of the drug and the development of toxic effects. In order to test the accuracy of this view Drs. S. J. Meltzer and W. Salant (*Journal of Experimental Medicine*, Vol. VI, No. 1, p. 107) undertook a series of experimental investigations, in the course of which they subjected rabbits, which are very sensitive to the effects of strychnine, to repeated injections beneath the skin of subminimum toxic doses at greater or lesser intervals. Following a preliminary series of control experiments, in which the limits of toxic and lethal dosage were determined, it was found that in animals from which the kidneys had been removed not only was the minimum toxic and fatal dosage not diminished, but also the repeated injection of subminimum doses, at not too short intervals, in amounts equal to fatal doses, was unattended with any reaction. Further, a single toxic dose caused but one attack, or at most a few attacks, of tetanus. The explanation of these apparently paradoxical results must reside in vicarious elimination on the part of other organs than the kidneys, or in the destruction of the strychnine in the blood, or in the development of substances that neutralize the effects of strychnine upon the nervous system, or finally in impaired absorption from the subcutaneous tissues by reason of increased blood-pressure. Which of these, one or more, is the responsible factor is a matter for future investigation. The practical value of the observations here briefly outlined resides in the demonstration that the removal, and probably also the destruction or the disease, of an organ does not necessarily result in the retention of the substances that it is known it is the function of that organ to eliminate.

ALCOHOLISM AND SUICIDE.

The Hospital, March 15, gives excerpts from an article on the above subject by Dr. W. C. Sullivan of Pentonville Prison, which appeared in the *Journal of Mental Science* (April, 1900).

The relation of alcoholism to suicide is a matter which has exercised the minds of alienists for many years, and especially of late, when the tendency to self-destruction seems to have become more pronounced than ever.

Dr. Sullivan states that in his article an attempt is made "to determine the rôle which alcohol may have played in the late increase of suicide in England and at establishing the distinctive characters which constitute the type of alcoholic suicide.

Authorities differ widely as to whether or not alcohol is a prominent factor in causing suicide. Dr. Magnus Huss states "that the suicidal impulse is a more frequent accompaniment of the melancholia of drunkards than of melancholia from other causes; and, further, that among the uneducated suicide frequently follows on the disordered emotional tone which, sooner or later, results from the abuse of alcoholic liquors."

The majority of observers are in accordance with these views, but there are some very distinguished investigators who hold that alcoholism has little or no influence upon suicide causation.

Dr. Sullivan himself believes that alcoholism is but one of the several causes of suicide, and that its relative importance as a suicidal factor differs in different places and at different epochs. In thirty years the increase of alcoholism in Great Britain is estimated at more than 100 per cent. During the same period there has been a steady increase in the suicide rate. As regards attempts to commit suicide, there has been a similar and even more decided increase. Voluminous and convincing statistical evidence proves these two points. It is likewise shown by Dr. Tatham's tables of occupational groups, with a high rate of alcoholism that these groups furnish a relatively high rate of suicide. Dr. Sullivan, therefore, draws the following conclusions: Firstly, that the recent increase of suicide has coincided with a considerable development of abortive suicidal attempts. These attempts, in such of their characters as are ascertainable, have approximated to the type of alcoholic suicide, thereby confirming the clinical evidence, which attributes to alcoholism the chief rôle in the genesis of abortive suicidal impulses. Second, that this increase of suicide has been, in a large degree, related to the influence of alcoholism, an influence which in the same period—as mortality statistics attest—has tended to augment. Third, that there is a type of alcoholic suicide, with characteristics distinguishing it from suicide of other causation, and that as compared with cases of deliberate and co-ordinate suicide due to other causes, alcoholic suicide is found to be more impulsive, more directly and immediately related to organic conditions in the individual. Fourth, the chronic intoxication by alcohol, as we observe it, clinically produces generalized disorders of visceral function throughout the economy, whence there results an alteration and disturbance of those organic stimuli which form the groundwork of our personality; those stimuli whose activity, as Maudsley puts it, is "even of more consequence in determining the tone of our feeling or of our disposition and the character of our impulses than that activity which follows impressions received from the external world." The depressed emotional tone thereby induced prepares the suicidal impulse, which issues into action when a supervening increase of intoxication has still further lowered the level of function in the brain.

RESTORATION OF DR. EDWARD KERSHNER TO HIS RANK IN THE NAVY.

We are much gratified to be able to announce to our readers that the President of the United States has signed the bill restoring Dr. Edward Kershner to his rank in the Navy, that of Medical Inspector. Dr. Kershner was dismissed from the service in 1896, after a court-martial, in which he was found guilty of violation of regulations, and scandalous conduct. The former statement meant that he wrote to his family and friends concerning charges of a serious nature, which afterwards were proven to be utterly unfounded, that were made against him by a high official of the line, who seems to have been very much incensed that Dr. Kershner had different opinion from himself as to the methods of spreading contagious or infectious disease. The second charge was in reference to his answers at the court inquiry, in regard to these communications. The proceedings of this court of inquiry, which, of course, preceded the court martial, were taken down in longhand, a fact which caused considerable discrepancy of statement by one or more of the witnesses against Dr. Kershner at the court-martial, and more serious results, as regards Dr. Kershner. The Senate twice recommended the restoration of Dr. Kershner, and finally the House of Representatives also unanimously made the same recommendation, and about March 20th, a few days after the passage of the bill, the President signed it, although, as we happen to know, some very high officials in the Navy were opposed to the last to Dr. Kershner's restoration.

This is, indeed, a triumph of right and justice. Dr. Kershner was never guilty of anything that ought to have subjected him to a court-martial. If every officer of the Navy who gets into trouble with his superior officer, and is made the subject of a court of inquiry on that account, should be punished because he writes to the Surgeon-General of the Navy and other friends in regard to the matter in question, the whole Navy would be under trial about half the time. This was all there was of Dr. Kershner's offense, for which he was dismissed from the Navy, although the evidence, according to many competent authorities, would never have passed in any ordinary court of justice.

As a matter of fact, a court-martial in the army or navy is a relic of feudalism, which could well be replaced by modern methods of learning the truth. The punishment inflicted on Dr. Kershner for an offense that was, at the most, merely technical—an offence committed at some time or other by every officer—was out of all proportion, even to the gravity of the matter—as determined by line officers. We are free to say that, under the same circumstances, an officer not connected with the medical staff and in the line would probably have been, at the most, reprimanded in general orders.

The charge of "scandalous conduct" was completely disproved by committees of Congress—a fact which is attested by the endorsement of President Roosevelt, who never would have restored Dr. Kershner to the Navy unless he knew that it was an act of justice to do so. We congratulate the profession that one of its honored members has been finally relieved from unjust and false accusations.

But six years is a long time to wait for such a result. It is proper to add that none of Dr. Kershner's colleagues in the profession ever seemed to have, for one moment, doubted Dr. Kershner's integrity. He is an honored Fellow of the Academy of Medicine, and Professor Emeritus in the Post-Graduate Medical School.

NUTRITION AND THE NUTRITIVE VALUE OF FOOD.

The U. S. Department of Agriculture has recently published a bulletin by Professor W. O. Atwater on the principles of nutrition and the nutritive value of food.

The pamphlet is a compendium of useful knowledge, and fairly bristles with facts with regard to nutrition and food. The professor sums up, in part, as follows:

Food has been briefly defined as "that which taken into the body either builds tissue or yields energy." After explaining the functions of protein and of the fats and carbohydrates, it is shown that the carbohydrates, as a general rule, are more fully available for use in the body than protein and fats, and protein of animal foods, as meat, fish, milk, and eggs is more digestible than that of vegetable foods. The need of proper cooking and of providing appetizing food is strongly insisted upon, and the beneficial results of a varied diet is clearly demonstrated.

Professor Atwater points out that as the habits and conditions of individuals differ, so, too, their needs for nourishment differ, and their food should be adapted to their particular requirements. It has been estimated that an average man at moderately active labor, like a carpenter or mason, should have about 115 grams or 0.25 pound of available protein and sufficient fuel ingredients in addition to make the value of the whole diet 3,500 calories; while a man at sedentary employment would be well nourished with 92 grams or 0.20 pound of available protein and enough fats and carbohydrates in addition to yield 2,700 calories of energy. The demands, however, are variable, increasing or decreasing with increase or decrease of muscular work, or as other needs of the person change. Each person, too, should learn by experience what kinds of food yield him nourishment with the least discomfort, and should avoid those which do not agree with him.

A Southern Physician's View of the Future of the Negro

The negro question cannot fail to interest an earnest American whether regarded from a political, social, moral, or physical standpoint. With the three first of these a medical journal has no direct concern, although there is a more or less intimate connection between each.

The health of the negro is, however, a matter of professional regard to medical men, and one which has, within recent years, been the cause of much discussion.

Opinions vary as to whether the negro has improved or retrograded physically since his freedom. The larger number of those competent to judge declare that the colored race in the United States is decidedly less hardy and less prolific than before the civil war.

Dr. Seale Harris, Union Springs, Ala., read before the Tri-State Medical Society of Georgia, Alabama, and Tennessee, at Nashville, on October 9, 1901, a paper on the subject, and commenced by saying that the negro race was the "white man's burden." He stated that after six years' experience as health officer and practising physician in a county where the blacks outnumbered the whites by four to one, he was saddened by watching the ravages of tuberculosis, typhoid fever, syphilis, and other diseases upon this generally kind-hearted and inoffensive people.

He called attention to the fact that before the war the negro death-rate in the South was less than that for the whites, while recent statistics of most cities of the South showed a negro death-rate of two to three times that of the whites, and in no Southern city did the negro birth-rate equal their death-rate.

Dr. Harris is of the opinion that "the three D's, dirt, disease and the devil, will be the principal agents in settling the question which faces the South. The writer does not credit the mortality statistics of the 1900 census, at the same time agreeing that there has been a considerable increase in the negro population, more than counterbalanced, however, in his opinion by the moral and physical retrogression of the race.

Tuberculosis, syphilis, and malarial fevers are the chief causes of the negro excessive death-rate and physical deterioration, but this Southern physician asserts that all diseases are on the increase with them, and further makes this important statement that while he has no statistics to show the mortality of carcinoma among the blacks, he believes it to be increasing among them at the same rate at least as among the whites.

As to remedies for such an appalling condition of affairs, none, thinks the writer, can save the negro from racial extinction. Nevertheless, according to his views, whatever is done should be effected in the way of sanitary reforms, and provision of free hospitals, sanatorias, and dispensaries for the treatment of their sick, rather than in spending thousands in training their minds.

The Prevention of Consumption

The Pennsylvania Society for the Prevention of Tuberculosis has recently published its annual report, and, it being the tenth year of its existence, gives a review of the work done during that period.

"La Ligue Contra la Tuberculose en France," founded in Bordeaux in 1891, was the first society of its kind. The Pennsylvania Society, founded in 1892, was the second and the pioneer in America. The National Society for the Prevention of Consumption and other forms of Tuberculosis was founded in London in 1898.

Among the most useful efforts of the Pennsylvania Society has been the publication of a series of tracts for gratuitous distribution intended to educate the general public as to the best means to be taken to avoid the contraction of tuberculosis and to prevent its spread. During the past year the Society has reprinted over 30,000 copies of its tracts, and has printed a new one.

In connection with another society, the Free Hospital for Poor Consumptives, a site for a sanitarium has been acquired and contracts for three buildings, having a capacity of forty-eight patients, have been awarded. With the present accommodations the institution will be able to care for seventy-five patients.

During the past year the Society has renewed its efforts to have pulmonary tuberculosis included among the diseases returnable to the Bureau of Health, but although endorsed by the Philadelphia County Medical Society, by the Bureau of Health, and by the Director of Public Safety, the measure was not adopted, owing to the adverse action of the Mayor.

A proposal by the Society to abate the spitting nuisance in Philadelphia by proceeding by law against offenders was also disapproved by the Mayor, and consequently came to naught.

The Society during its ten years of existence, by the energetic attempts to check the spread of tuberculosis, has thoroughly justified its foundation, and set an excellent example to philanthropists and sanitarians of other large American cities.

Cancer Among the Jews

When, some few weeks ago, Dr. Brathwaite of Leeds, England, advanced the theory that salt was a potent cause of cancer, and gave as one of the reasons for his belief in this supposition that the Jews, who consumed but little salt, were, as a race, remarkably free from cancer, the veracity of his statement was questioned by a large number of medical men who had had experience in Jewish practice.

In the *British Medical Journal*, March 15, the assertion is once more traversed in an able, although somewhat lengthy, article.

The writer, who is undoubtedly himself a Jew, says that in a practice, largely among Jews, extending over a period of more than twenty-five years, he has found ample evidence to show that individuals of the Jewish race are by no means free from carcinomatous disease. Mammary scirrhus has been very often met with, and while examples of nearly every form of cancer have been seen, there seemed to be a special tendency to the development of intestinal malignant growths.

The writer goes on to say: "Of patients dying between forty and sixty-five years of age a very large percentage have been sufferers from cancer, while it is sad to remember how many Jewish friends and relatives have succumbed to the same fell malady. There is undoubtedly an impression in the minds of members of the Jewish community that, far from being exempt, the Jews are especially prone to suffer from malignant growths."

Numerous statistics with regard to cancer among Jews in London are given, and from these the writer draws the following deductions:

It appears, then, on careful consideration, that the statistics of mortality from cancer among the Jews are not so much in opposition to the results of private observation as at first appeared, and the conclusion to be drawn from all facts at present obtainable seems to be that, while cancer is considerably less prevalent among Jews than among the general population, nevertheless, the probability that a Jew of cancer age will suffer from that disease is not materially less than in the case of a person of another race.

Moreover, the idea that the consumption of pork may be a cause of cancer can certainly be dismissed. At the present time a considerable number of Jews are by no means strict adherents to the dietary laws, and it will be within the experience of every one who has practised among them that cancer attacks the orthodox as often as it attacks the most heterodox of the race. That food has an important bearing on the causation of cancer would appear to be a belief that is steadily gaining ground among students of the subject. Behla is of the opinion that uncooked vegetables carry the infection; others variously surmise that pork, salt, or tomatoes are responsible for the conveyance of the disease. If, then, it can be proved that any one article or articles of diet are the infective agents, a very important step will have been taken toward the final solution of the cancer problem.

Mosquitos and Malaria.

Press despatches from Japan state that remarkable results have been obtained relative to the mode of infection in malarial disease by experiments conducted by the Japanese military authorities in Formosa. A battalion of soldiers, completely protected from mosquitos for 161 days during the malarial season, escaped the disease entirely, whereas there were 259 cases of malaria in an unprotected battalion in the same place and during the same length of time. These results, if correctly quoted, confirm in a most conclusive way the fact that malaria can be transmitted only by means of the mosquito, and call for the establishment of organized effort for the extermination of these annoying and pestiferous insects in malarial localities. That such a comprehensive test, so valuable in its results, should be carried out by the Japanese is evidence of acquaintance with and interest in the latest advances of medical science.

Is Influenza Preventible?

Dr. Robert Bell, an English physician, has advanced the opinion that influenza is a preventible disease, and his views are commented on favorably in a well-written article which appeared in the *Sanitary Record*, March 15.

Dr. Bell says that the principal factors which predispose to influenza are constipation, defective ventilation, overfatigue, prolonged strain of mind and body, insufficient food and clothing, and prolonged exposure to cold and wet.

The fact that influenza is more prevalent in winter than in summer is due, as Dr. Bell points out, not to the fact that the germs are more in evidence during one season than another, but simply because they have better facilities for developing their potency. These opportunities are the natural outcome of defective ventilation. The public are, unfortunately, prejudiced against fresh air, preferring a stuffy atmosphere; but if a perfect system of ventilation were made compulsory in all public buildings, the immunity from diseases such as influenza would soon convince them of the error of their ways, and speedily lead to a more intelligent conception of what ventilation means.

Dr. Bell also takes a tilt against the bad ventilation of railway carriages, and if he lived in this country, there is little doubt but that he would declaim quite as loudly, and with as much justice, against the street cars as propagators and disseminators of influenza and other kindred maladies.

As to whether influenza could be entirely prevented is, however, a question very difficult to answer. Being of microbic origin, and possibly air-borne, the malady travels from place to place and from country to country with incredible and disconcerting swiftness, and attacks those whose systems are run down and whose condition is low.

That its ravages might be greatly checked if people would live a healthy life, is patent to everyone. So far as defective ventilation is concerned, the remarks of Dr. Bell are perfectly correct, and apply, perhaps, with more emphasis to this country than to England.

The Medical Record has always insisted that the ill-ventilated and overheated public offices and rooms are responsible for many complaints of the respiratory organs, and are in particular eminently favorable to the incubation and spread of the germ of grip.

If influenza be not absolutely preventible, at any rate a careful observance of the ordinary rules of health will keep the insidious foe at a distance.

The Rank of Hospital Stewards of Marine Hospital Service.

A combined effort is being made by the former hospital stewards of the Marine Hospital Service, who were quite recently given the title of "pharmacists," to have this latter designation changed to "lieutenant," and to be given the rank and pay of lieutenants in the army. The movement is being supported by pharmaceutical associations in all parts of the country, and a number of petitions favoring this change have been received by Congress. Inasmuch as the Marine Hospital Service is not a military organization, and as the able physicians who constitute its commissioned personnel themselves have no military rank or title, it is scarcely to be expected that the latter would be granted to their subordinates, who have practically the same duties and status as the hospital stewards of the army and the pharmacists of the navy, neither of whom have the rank and pay of lieutenants.

The Philippines Constabulary and Army Medical Staff.—An order has recently been issued that sick officers and men of the Philippines constabulary receive medical attention at army hospitals, thus materially increasing the duties of army medical officers. Reimbursement for the cost of care, subsistence and medicines is to be made to the Medical Department from the constabulary appropriation of the insular funds, at the rate of $1 per day for each officer and 40 cents a day, United States currency, for enlisted men. This action is rendered necessary from the almost total lack of proper civil hospitals in the Philippines, and the great difficulty in securing competent medical attendance from the native physicians.

News of the Week.

Change in the Lunacy Bill.—A supplemental lunacy bill was passed by the Legislature just before its adjournment by which the provision of the former bill, to which we objected, was reconsidered and reversed so that matters remain, in so far as the continuance of the two superintendents on Ward's Island is concerned, as before.

Fire Precautions at Bellevue.—The *New York Evening Post* says that plans are being prepared which, in accordance with the demands of the Department of Buildings, will tend greatly to reduce the chances of fire disaster in Bellevue Hospital. A thorough inspection of the Bellevue buildings was made by the Department of Buildings, and the reports which followed recommended a large amount of work on the hospital structures.

Among others, these orders were issued by the Department after receipt of the report of the inspectors: The fireproofing of the elevator shaft, the removal of a wooden duct in the linen room, the removal of lath and plaster partitions near the amphitheatre of the main building, and the construction of an extra line of stairs from the balcony of the east wing to the main building. The erection of self-closing fireproof doors was ordered in all stories of the east wing, and in the hallway leading from the women's ward to the children's ward. Bellevue is already fitted with fireproof doors, but many of these were found to close imperfectly. Springs have been ordered for these. Fire escapes were ordered to be built on the front of the hospital ward at the second story; the platform to be four feet six inches wide, taking in three windows, with iron stairs to the ground, and on the east side of the annex.

Surgeons' Fees in France.—Dr. Albarran, one of the most prominent surgeons in France, recently sought to recover from a grocer the sum of $1,200 as a fee for performing laparotomy on the latter's wife. The Seine Civil Tribunal decided that the charge was exorbitant and reduced the fee to $500, at the same time recording the opinion that it is a medical man's duty to regulate his fee according to the means of the patient.

London Census Returns.—Details of the London census now issued give some interesting facts. The number of families in the metropolis is 1,019,546, and the average in a family is slightly over 4.4 persons. These families share the services of 234,398 female and 15,425 male servants.

In London females exceed the males by 252,371. Widowers are returned as numbering 72,128, while widows are nearly thrice that number. The youngest couple, husband and wife, are both sixteen, and the youngest wife in London is fifteen. The pauper inmates of work-houses are given as 46,646.

The percentage of the total population of the age of ten and upward engaged in trade or occupations is 83.6 per cent. of men, and 37.4 per cent. of women. The number engaged in electrical work has increased 16.6 per cent., and the actors, who total 2,234, show an increase of 78 per cent. compared with 1891. Women occupied in commercial business and as clerks have increased 181 per cent., and make a total of 19,097, compared with 84,315 males similarly employed. Foreigners who have not been naturalized total 135,377, and of these Russians are the most numerous, numbering 38,117. These are followed by Germans, Russian Poles and citizens of France and Italy.

Of the Americans who have not been naturalized, actors figure most conspicuously, numbering 211, three-fifths of the total profession being similarly ranked by the census as of [illegible] other occupations.—*New York Sun.*

Army Medical Officers Retired.—First Lieutenant Marshall M. Cloud, assistant surgeon, has been retired with the rank of captain, having been found physically disqualified for promotion. He has been in the army since 1896.

Colonel James P. Kimball of the Medical Department, who has been in the regular service since 1867, has also been retired. He was graduated from the Army Medical College and was promoted to be colonel January 1, 1902.

Cholera in Manila.—To prevent the spread of the cholera epidemic which prevails in Manila to the officers and men of the naval station at Cavite, authority has been given the ranking naval officer to take such steps as may be necessary. As far as can be learned, the epidemic is confined to the natives and Chinese in Manila, and the disease does not prevail among the whites.

The Medical Society of the State of West Virginia will hold its thirty-fifth annual meeting at Parkersburg, W. Va., on Wednesday, Thursday, and Friday, May 21, 22, and 23, 1902. Members are requested to send the titles of their papers to the Secretary not later than April 25, so that the program can be completed in time. The committee on arrangements, and other officers of the society, are sparing no effort to make the coming meeting one of great profit and pleasure to all. A very large attendance is, therefore, confidently expected. The usual reduced hotel and railroad rates will be granted.

Program and further details will be sent two weeks before the meeting.

The Association of Medical Officers of the Army and Navy of the Confederacy will meet in the Judicial Room of the City Hall in Dallas, Tex., corner of Akard and Commerce streets, on Tuesday, April 22, 1902, at 12 M. A grand reunion is expected, and extensive preparations are being made for a profitable and enjoyable interchange of past experiences.

Canadian Medical Association.—The annual meeting of the Canadian Medical Association will be heldin Montreal on the 16th, 17th, and 18th of September, 1902. The President is Dr. Francis J. Shepherd, 152 Mansfield Street, Montreal, the Local Secretary, Dr. C. F. Martin, 33 Durocher Street, Montreal, and the General Secretary, Dr. George Elliott, 129 John Street, Toronto. Dr. William Osler, Professor of Medicine in Johns Hopkins University, will deliver the address in medicine, and Dr. John Stewart, Halifax, N. S., the address in surgery. Arrangements are already well in hand for a very large meeting.

Philadelphia County Medical Society.—At a stated meeting held March 26, Dr. L. Napoleon Boston read a paper entitled "Amœbic Dysentery with Hepatic Abscess, Rupture into the Lung; Amœbæ Coli Found in the Sputum," and he exhibited the patient. Dr. Wm. Osler of Baltimore, by invitation, read a paper entitled "Amœbic Dysentery." Dr. Simon Flexner read a paper entitled "Bacillary Dysentery," and Dr. Hobart A. Hare one on "The Treatment of Dysentery."

Passengers Vaccinated Nolens Volens.—Twenty-five passengers on a south-bound Fordham trolley car had an unpleasant experience on Thursday, March 28, owing to the ill-advised zeal of a physician traveller. One of the passengers had a rash on his face, which was diagnosed as smallpox by a passenger, who said he was a physician and who ordered the motorman to proceed at full speed to the nearest police station. The car was forthwith sent to a police station, the man with the rash placed under guard, and the Health Department telephoned to for a vaccinator. A vaccinator was despatched and commenced to vaccinate the passengers without delay. Some objected, but their scruples were overcome and all submitted to the operation. The health physician then inspected the smallpox case, and immediately saw that the man had been wrongly suspected. It is said that the too-zealous physician received many back-handed compliments from the irate vaccinated ones, some of whom expressed their wish that he would go to a place where rashes are common and fools plenty. The doctor very wisely refused to give his name, and demurely disappeared to avoid a one-sided argument.

New York School of Clinical Medicine.—Dr. Robert Coleman Kemp of this city has been elected an Associate Professor in the Department of Internal Medicine, with Dr. A. W. Gardner as assistant.

Funds for Hospitals.—The Distributing Committee of the Hospital Saturday and Sunday Fund has decided to apportion this year's collections as follows:

Montefiore Home and Hospital for Chronic invalids	$6,600 00
St. Luke's Hospital	6,038 05
Mt. Sinai Hospital	5,351 55
Roosevelt Hospital	4,346 31
German Hospital	3,823 91
Hospital for Ruptured and Crippled	3,504 91
Mother's Home of the Sisters of Misercordia	2,569 31
St. Mary's Free Hospital for Children	2,261 76
Isabella Heimath	2,231 57
Nursery and Child's Hospital	2,188 19
Post-Graduate Hospital	2,143 41
Home for Incurables	1,877 75
Sloane Maternity Hospital	1,793 83
Lebanon Hospital	1,777 73
French Hospital	1,681 15
Colored Home and Hospital	1,610 11
Orthopædic Dispensary and Hospital	1,467 56
Homœopathic College and Hospital	1,464 23
New York Infant Asylum	1,323 57
House of the Holy Comforter	1,152 09
New York Eye and Ear Infirmary	1,097 86
N. Y. Infirmary for Women and Children	1,082 26
Woman's Hospital	998 57
Skin and Cancer Hospital	880 61
J. Hood Wright Memorial Hospital	875 54
New York Ophthalmic Hospital	790 09
Hahnemann Hospital	685 51
New York Polyclinic Hospital	643 94
Manhattan Eye and Ear Hospital	634 69
St. Mark's Hospital	608 40
Beth Israel Hospital	547 26
Loomis Sanitarium, city branch	501 95
General Memorial Hospital	446 30
Babies' Hospital	250 00
Convalescent Home	250 00
N. Y. College and Hospital for Women	250 00
N. Y. Ophthalmic and Aural Institute	250 00
Total	$66,000 00

X-Rays and Cancer.—It is reported that Dr. F. T. Addyman of St. George's Hospital, London, has announced that he has completely cured a bad case of cancer by the use of x-rays.

Deaths from Cholera in Manila.—The New York *Sun*, March 28, contains a despatch from Manila, dated March 27, stating that the cholera returns show that there have been sixty-three cases and forty-nine deaths since the outbreak. Two thousand persons are comfortably housed at the detention camp.

Played Piano for Twenty-seven Hours.—A despatch from Marseilles, March 25, states that a Mr. Garnier undertook to play continuously for twenty-seven hours, at intervals not exceeding in the aggregate an hour and a half, for a wager of 1,000 francs.

He succeeded in accomplishing his self-imposed task, but at the cost of considerable nervous energy, and with much severe physical suffering. When he stopped, having won his wager with fourteen minutes to spare, he collapsed from nervous prostration. The condition of his hearers has not been given.

Expectorators in Public Places Fined.—About a week ago fifty spitters were tried at Special Sessions. Eighteen were discharged because at the time of the arrest they had been locked up for six hours or longer. The remainder were fined $5 each.

New York City Health Board Oppose New Tenement Clause.—The Health Board has opposed the amendment to the Tenement House Bill adopted by the Rules Committee of the Assembly, modifying a section of the bill calling for larger airshafts and better ventilation in tenement houses, on the grounds that such an amendment would be antagonistic to the best interests of the public health.

The Birthplace of Christian Science Bought.—The old house in Lynn, Mass., where Mrs. Eddy wrote her work, "Science and Health," the genesis of the cult, has been purchased by her followers, and will be used to provide a church home for the faithful, and will be maintained as a memorial to the prophet of the doctrine.

Yellow Fever in the British Garrison at Jamaica.—The American Consul at Kingston, Jamaica, has informed the State Department that yellow fever has broken out there, three British soldiers having been attacked with the disease. The remainder of the garrison has been removed to the mountains.

Smallpox in Antwerp and Brussels.—It is reported that smallpox has broken out severely in Antwerp and Brussels, and the report goes on to say that the disease was imported from London.

Professor Virchow Much Improved in Health.—Professor Virchow's health is now said to be quite satisfactory. The fracture of the femur has united, and he gets up every day, but, considering his age, the probability of a resumption of his lectures is not great.

New Feature of the Edinburgh Medical Journal.—In the March number of the *Edinburgh Medical Journal* a new departure is made. The original articles are preceded by a number of short and pithy editorial notes, which much enhance the interest of an already excellent journal.

Cholera Increasing in Canton, China.—A telegram received by the Department of State for the information of the Marine Hospital Service from the U. S. Consul at Canton, dated March 6, reported that cholera in that city was increasing. Customs Club closed and employees were ordered to live on boats on the river.

Enteric Fever in South Africa.—According to the official statement, during the month of December last the admissions for enteric fever among the British forces in South Africa were 1,507, and the deaths were 224. The figures for January are not yet complete.

Pathological Society of Philadelphia.—At a stated meeting, held March 27, Dr. A. C. Croftan presented a communication entitled "Calcium and Tuberculosis," in the course of which he suggested that an antagonism exists between the chemical substance and the disease named. Dr. Alfred Stengel reported two cases of malignant endocarditis with isolation of the streptococcus pyogenes and the bacillus aerogenes capsulatus from the blood and the tissues. In one of the cases the symptoms were suggestive of exophthalmic goiter, but the fever and the leukocytosis pointed to the existence of an inflammatory process. In the second case articular symptoms suggestive of rheumatism were present. Dr. E. K. Moore made the report of a case of meningitis due to the typhoid bacillus. The diagnosis was confirmed by the anatomical and bacteriological findings after death. Dr. N. B. Gwyn exhibited a macroscopical specimen of carcinoma removed during paracentesis abdominis. Dr. J. F. Schamberg made a preliminary report on micro-bacilli in the sebaceous follicles of the nose with demonstration of the alleged germ of seborrhea and baldness. Dr. Augustus A. Eshner exhibited a specimen of carcinoma of the stomach causing pyloric obstruction and followed by diffuse extension to the peritoneum.

Obituary Notes.—Dr. GERALD O'FARRELL died suddenly, on March 27, in Philadelphia, at the age of seventy years. He was graduated from the medical department of the University of Pennsylvania in 1862. He enlisted in the army and served throughout the Civil War as Surgeon to the 63d and 215th Regiments Pennsylvania Volunteers.

Dr. MOSES T. BABCOCK, who had practised medicine in Hammondsport, N. Y., for fifty years, died suddenly on March 31. He was seventy-seven years old, and during the civil war was an assistant surgeon.

THOMAS DUNN ENGLISH, physician, poet, and author of "Ben Bolt," died in Newark, N. J., April 1, aged eighty-three years. He was born in Philadelphia on June 29, 1819, and was graduated in medicine from the University of Pennsylvania at the age of twenty. He took up the study of law, and three years later was admitted to the bar in Philadelphia. He had been fond of literature from the time he was sixteen, and desired to become a writer. In 1843, when he was twenty-four, he wrote the poem by which he is most widely and popularly known, but he did not name it. N. P. Willis and George P. Morris were then running the *New Mirror* in New York, and Willis, who knew English, asked him to write a poem for the publication. English wrote a sea song which he didn't like and tore it up. He set to work again and wrote the poem now known as "Ben Bolt," to which he appended the last four lines of the first poem, the only lines in it which he had liked. This second product so little pleased him that he sent it to Willis with a letter telling him that if he didn't like it he could tear it up. Strange to say, in his late years he was greatly annoyed by his fame as the author of one of the sweetest poems in literature.

Dr. GERHARD LOELING died of heart disease, on March 23, in Philadelphia, at the age of seventy-one years. He was the son of an eminent Prussian surgeon and was a graduate of German universities. He came to the United States in 1864, and was graduated from Jefferson Medical College.

Dr. THOMAS S. BUTCHER, formerly of Philadelphia, died at Monterey, Mex., on March 17, at the age of fifty-five years. He was a graduate of Jefferson Medical College, and had resided in Mexico for about fifteen years.

Dr. URIAH GILMAN, the oldest practising physician of Woodstown, N. J., died suddenly, from heart-failure, on March 24, while engaged in extinguishing a fire on his farm.

Dr. WILLIAM ELLIOTT HUGHES, Jr., who was formerly an assistant on the surgical staff at the Johns Hopkins Hospital, and later practised in partnership with Dr. Young at Baltimore, died, on March 20, of typhoid fever, at Johns Hopkins Hospital. He graduated from the University of Virginia, and studied medicine in the Johns Hopkins Medical School.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENT COMMITTEE ON MIDWIVES—DEFECTIVE EXAMINATION OF YEOMANRY EXPLAINED—CONSCIENTIOUS OBJECTOR CLASS—EDUCATION BOARD AND REVACCINATION—PERITONITIS FROM RUPTURED OVARIAN ABSCESS—INTUSSUSCEPTION—SMALLPOX—FELLOWSHIP ROYAL SOCIETY—THE LATE DR. [illegible].

LONDON, March 15, 1902.

THE Standing Committee on Law has made progress with the Midwives Bill. Its advocates, deaf to all remonstrances, are forcing it through the committee without substantial change. The Obstetrical Society's certificate is to be recognized as a qualification—its illegal action thus being legalized. And yet the Rotunda Hospital, which has a charter and is second to no school in the world, is to be left out. It is thus obvious that the Obstetrical Society is the center of the fight. All the advocates of the bill are defenders of the society and all its works, and yet every medical reformer denounces the society's corrupt diploma trafficking, and regrets that the Medical Council climbed down when it threatened the traffickers. Unless the profession throws off its apathy without delay and makes its voice heard, the worst bill ever proposed on this subject has a chance of passing.

The Secretary of War, in reply to a question, has had to confess that he was not able to learn whether the late director-general of the medical department sanctioned the instructions issued to civil practitioners not to reject candidates for the yeomanry on account of minor defects, as he had been informed by the press that the director never saw them, and was never consulted on the subject. It is only another instance of the contempt of the military department towards other departments, and only comes to the surface in consequence of the war. The question of consulting the medical officers on sanitary matters will soon become a burning one. Think of sending armies into South Africa, a country where typhoid is endemic, without the precautions devised after the Crimean War!

Yesterday Mr. Long told the House that the Government did not intend to take any action respecting the "conscientious objector." He also replied to a question that officers of the education department had been invited to submit to revaccination. Those who did not, were to give their names to the heads of their sections. A minute was then issued inviting objectors to reconsider the matter before the board decided what further steps to take. This is taken as a threat, and notice is given of a question as to the powers of the board to compel their officials to be revaccinated. So we are threatened with another shriek for personal liberty to risk smallpox.

Dr. Comyns Berkeley showed to the Obstetrical Society the uterus and appendages of a patient who died from acute peritonitis, set up by rupture of an ovarian abscess, twelve hours after labor had ended. The woman had had five children, and this pregnancy was uneventful. She had never complained of abdominal pain, and her history was one of good health. At the early part of the labor there was some vomiting of a yellow fluid, with pulse 100, but respiration and temperature normal. Three hours later, pulse 136, respiration 30, vomiting continuing. Labor was soon completed; pulse fell to 80, respiration 30, temperature normal. Six hours later, collapse, continuous vomiting, pulse 136, respiration 60, no pain. Dr. Berkeley was then asked to see the case, and found the stomach very much dilated, reaching within two inches of the pubes, partly obliterating the liver dulness and compressing the left lung. Dr. Campbell Thompson, who lately read a paper on the subject, was asked to see the case, and agreed in the diagnosis of acute primary dilatation of the stomach. There was nothing to point to peritonitis, but the patient died six hours later, and the post mortem revealed a large amount of semi-purulent matter in the abdomen. The left ovary had an opening at its lower border, through which pus was escaping, and which led to an abscess cavity. The abscess had also burst into the broad ligament from an opening, in which there was a further escape of pus. The ovary was bound down by old adhesions to the posterior surface of the uterus. Dr. C. Thomson, who made the post mortem, thinks it confirms his opinion that acute primary dilatation of the stomach is allied to that of stomach and intestines sometimes met with in peritonitis. Dr. Berkeley suggested that the abscess had been burst by the contractures of the uterus.

Dr. Horrocks (president) remarked that, as a student, he learned from Dr. Fagge that there were three cases in which a woman in ordinary health might suddenly become very ill, viz., rupture of a gastric ulcer, of a latent typhoid ulcer, or of an ovarian abscess.

Dr. R. Boxall mentioned a case of a woman doing her washing on the tenth day after labor, but who died the next day. She had had no pain, but suppurative peritonitis was found at the post mortem.

Dr Handfield-Jones mentioned a case of sudden death, in which he found at the post mortem purulent peritonitis from a ruptured ovarian abscess.

Dr. Griffith alluded to the difficulty of distinguishing abscess of the ovary or tube antecedent to labor, and such an abscess forming part of a general infection at the time.

Dr. Eden suggested the possibility of an ovarian abscess resulting from bowel infection, and Dr. Targett from some traumatism of the cervix.

At the same meeting, Dr. V. Bouney showed a very rare specimen, viz., primary intussusception of the large intestine spontaneously passed by the patient, aged fifty-six years, who had a large ovarian tumor, also shown, removed at the post mortem five months after the expulsion of the portion of bowel.

Smallpox has continued. There were fifty fresh cases March 14, bringing the number in the hospitals up to over 1,600, the highest number yet recorded during the epidemic.

A new woman's grievance—she is not eligible for Fellowship of the Royal Society. She is, therefore, preparing to storm this ancient citadel of science. A plan of campaign is being arranged compelling a change in the rules. But should we not first be told who are the candidates for whom we should fight?

The death of Dr. J. Lumsden Propert, in his sixty-seventh year, recalls to mind the great work accomplished by his father, John Propert, the founder of the Royal Medical Benevolent College. Never was a nobler scheme more nobly carried out for the benefit of the profession than that of John Propert. Of course, the son also was deeply interested in the prosperity of the institution. He was a London graduate, a man of fine taste, a connoisseur in art, and a very good etcher He wrote a "History of Miniature Art." He had a large and select clientele. The funeral service was attended by many leaders in the profession.

OUR LETTER FROM SYRIA.

(From Our Special Correspondent.)

THE "SCHLOOK" AN ILL WIND—A MODEST DISCOVERER OF A CANCER MICROBE—SMALLPOX AND THE PLAGUE—"KIBBY," THE NATIVE FOOD—A VISIT TO THE HOSPITAL SHIP "MAINE."

BEYROUT, SYRIA, February 27, 1902.

As you know well, this town suffers from a characteristic monotone of insipid inertness, and will be pleased to hear that we, who are strangers and pilgrims in a very pleasant land, from a desire of living and burying ourselves, are being refreshed, and are likely to live a little longer.

Not to put too fine a point upon it, we are being entertained by what might be called a two-act undulating drama of Rain and "Schlook"—a kind of "Box and Cox" performance—when the one isn't with us the other is. The former, being a casual visitor, not making himself too common (to continue the metaphor), appearing for a few nights (and days) only, is always welcome, and his worth is appreciated by the Schloheen (the farmers), especially. With the latter (the "Schlook" — not the farmers) we shall have to deal more fully and, leaving metaphor, come to solid facts. Our style being too florid for descriptive purposes, we adopt that of a little friend of ours by the name of Little Johnny, who has been trained in literature on the familiar bases of Shakespeare and the family Bible. "Schlook," he says, "is a compound of all wickednesses, from the rising up of the sun to the going down thereof—from our getting up too early in the morning to our not being able to sit up too late at night. It is a wind that bloweth where it listeth, and nobody knows whence it cometh and whither it goeth. It is an incarnation of every evil wind that blows upon the face of the earth. It gives us a chance of catching every disease from the crown of our head to the sole of our feet, and if we don't catch diseases with it (*sic*), it makes us feel deadly sick of everthing and everybody. They say it's the famous 'Sirocco' wind that comes to visit us from the African desert. If it is 'famous,' it should retire before it gets stale; and if it is from Africa, Mr. Carnegie should give it a prize to stay at home. We don't want any 'Schlook' here. It's nearly as bad as the rats that 'fought the dogs, and killed the cats, and bored holes in meat vats' that Mr. Browning wrote about. If he were alive now, he would say something worse about 'Schlook.' His language is comparatively mild in comparison to that which I could use if I were permitted." So says Little Johnny, and we presume to agree with him. "Schlook" and all, and the infrequent visits of the rain, we have a pleasant enough climate, and, as we said before in a former letter, not by any means an unhealthy one.

By way of a change, we have occasional and intermittent outbreaks of the plague scare, which, more or less, disarranges our nervous systems and inclines us to go beyond the limits of our vocabulary; but it does not do us much harm.

A Christian sometimes kills a Moslem in the open market and in open daylight, and the compliment is returned after the manner of a *vendetta*, which gets so monotonous that the strong arm of the law sometimes gets tired of it, and, by way of a change, intervenes.

One of our physicians here, we are informed, told a patient of his that he had discovered the microbe of cancer in a tumor of her breast. As he has not shown it (the microbe), we presume he has kept it to himself, and are sorry we are not able to describe it. We are also sorry to say we are not in a position to report on the latest cancer cure—*essence of violets*, we believe it is called—as we have not yet been induced to use it. As there are plenty of cases of cancer in the town, we should be afraid, if this essence should come into vogue, that violets would go up so much in the market that we would be unable to purchase our customary buttonhole of our favorite flower.

Of all "the dread diseases that carry mortals home"—and, having mixed in the society of most of them, we ought to know—we think the dreadest of all is that just mentioned—not omitting his friend and companion, that runs him hard in the list of evils to be avoided: we refer to smallpox—surnamed "Jidra" here. We are almost beginning to forget the latter's familiar face, as neither the authorities (who are high and mighty in this place) nor the people, who are under them, appear to like the disease, and work together for its extermination, and, for some reason that Jenner knew—and may be now knows all about—gives us a wide berth. London, we are sorry to see by reports that come to us occasionally, has given it a friendly lead, and, for having shaken hands with it is now getting its deserts with a vengeance. London—we don't say all London, but those who are "mostly fools" in it—will (to use an old pantomime gag) "be sorry for it, if they are not already so." We refer more particularly to those in the big city who are suffering from a complaint nearly as bad as smallpox, to wit, stupidity—a malady, as the ancient poet tells us, that the gods themselves "fought against in vain."

We don't pretend to be prophets, but are assured if stupidity is allowed to run rampant in London it will indeed be that "bitterness in the latter end"—if not to us who know, to our children, and to those who may come after us.

We are now sitting in a pleasant little room in this pleasant month of February, compounded by a rain and hot wind. The thermometer (February ought to know better) stands at 70° F. in the shade, and overhead there is a sound of banging doors and windows and of whistling winds, which is almost disconcerting, and over and above all there is a pounding of something the people eat here that goes by the name of "Kibby" (a name that, by the way, in Egypt means the plague), which certainly deserves its name, and should be manufactured in some mill outside the camp. This "kibby"—or "kibeyel," as the Egyptians call it—is a well-beloved but very filling production made by pounding dry wheat and raw meat in a mortar, and the more noise they make the better flavor it must give, it seems. As an article of diet it has splendid staying powers, and requires a stomach in the acme of training to tackle it. However, it is well liked by the people, and, if they would only not make so much noise about it, we would not have a word to say against it.

Influenza may be upon us again later on; at present we only hear the beating of its wings. Plague, as an excitable quantity, is, for the time being, defunct, and cholera is as far off as the yellow haze that portends its coming. To wind up, they have mended two roads that were suffering from a chronic complaint of a complication of dust and mud, pitfalls, and obstacles left in the way, which were almost as irritating, if not as obnoxious, on dark nights as the whole gang—from the gentleman who preaches his doctrines from a barrel to the antivaccinationists.

We were almost closing without telling you that the hospital ship *Maine* came in here the other day, and we paid her a visit. The captain and officers (we were informed) were ashore, and the Staff Surgeon, Craig, was, at the time, engaged in entertaining a party of friends, so we were unable to see him. His henchman (of the rank of sergeant, we assume from the three stripes on his arm) took us around and showed us everything that was to be [illegible] it appears. There were twenty three sick aboard—one convalescing after an extirpation of the eye, which was the only case brought to our notice. The ship was as clean as a new pin; the lavatories were absolutely odorless—both officers' and men's—the latter, however, seem to have to "sit in a row," as there is no partition between the urinals—the officers being provided with separate little mahogany cabinets. The washing arrangements are interesting and handy, but the central wheel was wabbling so that it could not attain its 1,400 revolutions a minute, and could not be got into working order.

ELECTRICAL NERVE FORCE—PRIORITY OF CONCEPT.

To the Editor of the Medical Record:

Sir,—In a paper read to the Pennsylvania State Medical Society in September, 1900, and published, with drawings, in the *Pennsylvania Medical Journal* for November, 1900, I affirmed the identity of nerve force and electricity. The paper was entitled "Analogies between Nervous and Electric Mechanisms: What Is Nerve Force?" The same evidence and conclusion had been previously given by me to the Lackawanna County Medical Society, May 22, 1900, with the addition of the following statement: "The fact is, I believe, that every unit of muscle is surrounded by a field of force, the disturbance of which causes it to contract, and the same is probably true of every protoplasmic unit"—thus extending the electrical concept to muscle and living protoplasm generally. This extension I omitted from my paper to the State Society because I hoped that the first announcement of the concept would be more favorably received if limited to the nerves. Dr. L. Wehlau, then President of the County Society, Dr. Reed Burns, Dr. Gunster, and other members can attest the fact that it was included in the original paper of May 22, 1900.

In both papers, after citing all the evidence available and illustrating by many drawings, analogies between nervous and electrical mechanisms, I summarized the subject as follows:

"Nerves are constructed like electric cables. They are insulated, distributed, and arranged like fine electric conductors. Their purpose and use are the same as the purpose and use of electric conductors; namely, communication from point to point. They convey some form of force. It is probably electricity, because electricity is always present when they act. Because it is the form of force that would do the work required. Because it is the form of force that would work with such construction. Because the terminal and central mechanisms connected with the nerves correspond to the terminal and central mechanisms connected with electric systems of communication and do similar work in controlling, receiving, relaying, switching, transforming, accumulating, retarding, discharging, concentrating, distributing, and translating impressions. Finally, because electricity, with such construction of conductors and of terminal mechanisms, is the only form of force that we know of that would do all the work required.

"I therefore conclude that nerve force is electricity, that it is produced in the nervous system by chemical processes analogous to those which produce heat in the general tissues; i.e., oxidation, and that it would advance knowledge of the nervous system and its functions to acknowledge this proposition, at least as a working hypothesis."

With high appreciation of Professors Loeb and Mathews' work as most valuable additional evidence that nerve force is electrical (see "The Nature of the Nerve Impulse," by Prof. Mathews, in *The Century*, for March, 1902), and as supporting the extension of the electric concept to muscle and protoplasm generally, I ask any credit that may be due for priority in announcing positively the same conclusions, at which I had arrived before them by other but, I think, as certain paths.

These conclusions may have been guessed at before (though I have been unable to find that they have ever been logically affirmed), but I think my paper brought more and weightier evidence together than could have been done before, and clearly stated the logical necessity of the electrical concept. All physiologists were either committed against it, or ignored it.

Now, with new chemistry getting largely on an electric basis, I fully expect these lines of physiology to follow, in spite of the dull inertia of conservatism which has been repeating in almost every book and lecture for years that "Nerve force is not electricity," without giving or being able to give one logical reason for the negation.

J. Emmet O'Brien, M.D.

Scranton, Pa., March [illegible]

Book Reviews.

A Practical Guide to the Administration of Anæsthetics. By R. J. Probyn Williams, M.D., Senior Anæsthetist and Instructor in Anæsthetics at the London Hospital, etc. London, New York, and Bombay: Longmans, Green & Co., 1901.

In England more attention is perhaps paid to the subject of anæsthetics than in this country, where we have for some time been accustomed to regard ether as undoubtedly the safest substance of all which have been employed to obtain anæsthesia. This little volume is one of the most satisfactory and practical which we have met, and is concise and comprehensive. Much space is given to nitrous oxide alone, and in combination with ether according to the methods so much in vogue at present, and what the author considers the best forms of apparatus are thoroughly described. A chapter is devoted to the choice of the anæsthetic which is best for any given condition, and here, as elsewhere, the directions are clear and reasonable.

Parasitologie Animale. Par le Dr. Maurice Neveu-Lemaire, Préparateur au Laboratoire de Parasitologie de la Faculté de Médecine de Paris. 301 Figures dans le Texte, et une Préface par le Professeur R. Blanchard. Paris: Société d'Éditions Scientifiques, 1902.

This little brochure contains a systematic description in a condensed form of the different parasites which prey upon humanity and the lower animals. All the common and most of the rarer parasitic organisms are well illustrated, and, as far as is known, their life histories are given, making the work useful for the identification of any parasite with which we may be confronted. Such organisms as that of malaria, trichinosis, the various species of tapeworm and other intestinal worms, mosquitoes, and some of the less common dipterous insects, are among those to which most space is devoted. The present volume fills satisfactorily a place in a somewhat narrow field, and makes a satisfactory work of reference.

An Experimental and Clinical Research into Certain Problems Relating to Surgical Operations. Alvarenga Prize Essay, 1901. By Geo. W. Crile, A.M., M.D., Ph.D., Professor of Clinical Surgery, Medical Department, Western Reserve University, etc. Philadelphia: J. B. Lippincott Company, 1901.

The author of this essay has done a large amount of animal experimentation, and the present is his third publication in this field. A large number of experiments are detailed, mostly upon dogs, and many data of blood pressure, respiration, secretion, and drug action are collated. A number of observations upon human beings are also recorded and discussed, in which physiological experiments have been accidentally reproduced in the course of surgical work. Such accidents as division of the pneumogastric nerve are mentioned. It is interesting to note that the clinically beneficial action of saline infusion in conditions of shock and hemorrhage is also noted in experiments upon animals in whom vaso-motor tone is found to be decidedly increased by infusion, when it is not overwhelmingly diminished, to begin with. Many interesting observations upon animals under the action of cocaine and eucaine are also recorded, and a satisfactory summary of the deducible evidence is given. The volume contains a number of interesting pieces of information, but much of the laboratory detail may be passed over without perusal.

The Mental Functions of the Brain: an Investigation into Their Localization and Their Manifestation in Health and Disease. By Bernard Hollander, M.D. Illustrated. With clinical records of eight hundred cases of localized brain derangements, and with several plates. New York: G. P. Putnam's Sons, 1901.

Dr. Hollander puts at the top of his title page the words, "A Revival of Phrenology," and his book, as may be inferred, is apologetical and resuscitatory of that nearly extinct cult. Dr. Hollander is of the opinion that Dr. Gall was one of the greatest and most original of savants, that his merits have not been properly appreciated, nor the value of his discoveries and doctrines recognized. In pursuit of his purpose, the author has gone over a large amount of medical literature, collecting cases for the purpose of localizing topographically the different mental functions of the brain. He reports, for example, 150 cases of melancholia, and concludes that there is a certain relation between the inferior area of the parietal lobe—that is, the angular and supramarginal gyri—and the melancholic state. He then cites 350 cases of irascible insanity and furious mania and concludes that irascibility and violent, destructive manias are in relation with the middle part of the tempero-sphenoidal lobe. He cites forty-five cases of what he calls "mania of suspicion and persecution," but which would be perhaps classed as cases of systematized delusion or paranoia, and he thinks that lesions of the posterior temporal area of the brain give rise to such types of delusions.

Gall concluded, from his observations, that men who had an uncontrollable tendency to theft had the anterior part of the temporal region very prominent, and Hollander cites a number of cases of injury to the anterior part of the temporal lobe in persons suffering from kleptomania. The centers for voracious hunger and thirst are put down as being probably near the same region. The author thus throws the awful burden of theft, madness, and bad temper upon the temporal lobes.

Going on to the localization of speech and memory, Hollander claims that Gall first localized the speech center in the third frontal convolution at its basal extremity, and, as a matter of fact, this is not far from true, though Gall spoke of it under the vague term of "verbal memory." He cited a case of motoraphasia, also due to injury in this region. Gall placed the brain center for music very nearly over Broca's convolution; this is not far from the center for amusia in the temporal lobe. As regards the center for the memory of numbers, Hollander cites the observations of Möbius of Leipsic, who, in 1899, stated that he was convinced that Gall was completely right in his localization of the mathematical centers in the frontal lobes.

The author goes on to point the way for further investigations into the localization of functions. He suggests the centers for movements of the face and eyes as being in relation with the centers for exaltation, and that the center for firmness is in connection with that of the leg. He seems in some sympathy with Gall's idea that the cerebellum is the seat of sexual instinct, and calls in evidence the fact that excessive application to gymnastic exercises diminishes for a time the sexual desire.

Chapters are devoted to the subject of the relation between the brain and the skull, the significance of cranial contours and the doctrine of free will.

The book is illustrated with some colored plates indicating the localizations suggested by the author, which are really very much less radical than the text would lead one to infer.

We have given, perhaps, more space to this work than its scientific value deserves, for it practically has none; but it contains a good many clinical records, and the discussions have the interest and suggestiveness which always surround the history of a really great and original man, who founded a school that lived more than a generation.

A Manual of Medicine. Edited by W. H. Allchin, M.D., London. Vol. III., "Diseases of the Nervous System." The Macmillan Co., 1901.

This small volume contains a brief resumé of diseases of the nervous system by nine British contributors, as follows: Bertram Abrahams, M.D., Walter Stacy Coleman, M.D., James S. Collier, M.D., Joseph A. Ormerod, M.D., Charles S. Sherrington, Purves Stewart, M.D., James Taylor, M.D., William Aldren Turner, M.D., and William H. Allchin, M.D. The "Physiological Introduction" by Sherrington is exceptionally clear and concise, and the various clinical types of nervous diseases are accurately but briefly described. A novel feature, not usually found in other similar works, is the special chapter on "Medical Ophthalmology" by Taylor, in which conditions of the pupil and ocular fundus are described in their special neurological aspect. The authors have successfully accomplished a task, by no means easy, in placing before their readers an acceptable treatise on nervous diseases which seems to cover the entire subject, although in a very condensed manner. The book will satisfactorily serve its purpose as a manual for ready reference, and is a welcome addition to the various larger volumes on neurology published within the last few years.

Studies in Physiological Chemistry: Sheffield Scientific School of Yale University. Edited by R. H. Chittenden, Ph.D. New York: Chas. Scribner's Sons.

The volume before us is one of a series of publications celebrating Yale University's 200th anniversary, and is appropriately dedicated to the graduates of the university. The volume is composed of "reprints of the more important studies issued from the Laboratory of Physiological Chemistry," comprising work done during the years 1897 to 1900. An interesting bibliography of the Sheffield Laboratory, from its founding in 1875 to 1900, is prefixed to the volume. It will be impossible within the limits of this review to do more than touch upon what seems to us, from the medical viewpoint, the more important of the monographs. Of these, A Further Study of the Influence of Alcohol and Alcoholic Drinks Upon Digestion, with Especial Reference to Secretion, by Professor Chittenden, Lafayette B. Mendel, and Holmes C. Jackson; The Influence of Bile and Bile Salts on Pancreatic Proteolysis, by Professor Chittenden and Alice H. Albro; Of the Occurrence of Iodine in the Thymus and Thyroid Glands, by Lafayette B. Mendel, stand forth prominently.

Concerning alcohol, Professor Chittenden concludes that "gastric digestion in the broadest sense of the term is not markedly varied under the influence of alcohol or alcoholic fluids." This conclusion seems contrary to the universal belief of clinical men. A fact of practical application in the absorption of alcohol is established experimentally. "Thus an ordinary dose of chloral hydrate introduced in watery solution into a stomach with ligatured pylorus fails to bring about narcosis; if, however, a quantity of alcohol too small of itself to produce any pharmacological action be present, narcosis follows, just as when the open pylorus permits the intestine to participate in the absorption."

Essentials of Obstetrics. By Charles Jewett, A.M., M.D., Sc.D., Assisted by Harold F. Jewett. Philadelphia and New York: Lea Brothers & Co., 1901. 12mo, pp. 386.

The second edition of this work is a marked improvement upon the first, and presents in a concise and intelligible form all the elementary essentials of the subject.

Food Value of Meat. By W. R. C. Latson, M.D. 72 pp. New York: Health Culture Publishing Co.

This is an entertaining booklet, semi-scientific, written for the public, and as such interesting to the physician, purposing to convince the reader that many of the evils of life result from the use of meat, and that, by a proper knowledge of the combination of other foods, meat can be entirely dispensed with.

It contains nothing new for the physician, but it presents the physiological and chemical facts relating to the subject in a pleasing, readable manner. Excessive meat-eating is probably more prevalent in this country than in any other outside of England, and the general public can but benefit by being taught that many other foods are more healthful and as nourishing as meat. The little book can be read in an hour, but to those unacquainted with the chemistry of dietetics, its digestion might profitably last several months.

Le Cancer du Sein, Etude Clinique Statistique. Par A. Le Dentu, Professeur de Clinique Chirurgicale à la Faculté de Médecine, etc., avec huit figures. Paris: Librairie J. B. Baillière et Fils, 1902.

This clinical treatise contains the experiences and deductions of a noted French operator upon the subject of mammary carcinoma. The author takes up his own series of cases and describes his methods of operating, and his results, so far as he is able to give them. He has had a number of patients who have remained free from recurrence for long periods, but, apparently, no more than in similar series from other sources. The net result of the report is that those patients who are operated upon earliest in the disease, and most radically, have the best chance of immunity from recurrence. This is the conclusion of all modern operators. A chapter is devoted to descriptions of the various operative procedures which have been recommended for the radical removal of the carcinomatous breast, and details and indications are given.

A Manual of Venereal and Sexual Diseases. By Wm. A. Hackett, M.B., Ph.G., M.C.P.S. (Ont.), Professor of Dermatology and Venereal Diseases, Michigan College of Medicine and Surgery; Attending Physician to the Emergency Hospital, Detroit, etc., and N. E. Aronstam, M.D., Ph.G., Assistant in Chemistry and Clinical Dermatology, Michigan College of Medicine and Surgery, etc. Chicago: G. P. Engelhard & Company, 1901.

Like old Gaul this book is divided into four parts. Otherwise there is no close resemblance. For a book of its small page area, one finds the essentials concerning gonorrhœa, chancroid, syphilis, and sexual matters fairly well encompassed in the two hundred pages. Of course, a student's book should have this amount of space devoted to each separate division of the matter, and then it would not be a large book. The illustrations are limited to the usual instruments for genito-urinary work. While such a work may be useful as a "remembrancer" in the classes taught by the authors it takes altogether too superficial a view of a vast territory to be recommended as a text book to those preparing for practice, and hence would be of little use to one already in it.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 27, 1902

Sterilization of "Gum-Elastic" Catheters.—F. J. Cotton has experimented with ammonium sulphate and concentrated salt solutions for the purpose of sterilizing "gum elastic" catheters and bougies. As a result of these tests, the author claims that all such instruments may be boiled repeatedly and for long periods in saturated (or more than saturated) solutions of ammonium sulphate or sodium chloride without essential damage.

The Suture of Arteries.—J. C. Hubbard describes the technique of various methods which have been devised. In all these procedures absolute asepsis is necessary. The circulation must be controlled sufficiently far away from the injury to give room to work, and especially far away if a resection is to be done, but whatever the means employed the slightest pressure possible should be used to prevent bruising. The suture must just fill the hole made by the needle, and both must be the finest that can be handled. All clots must be removed from the wound in the artery. A continuous suture is recommended. Compression must first be removed from the distal end of the artery. This will let the blood flow back and test the suture before allowing full blood pressure against the stitches. Real bleeding can be again controlled by additional stitches; oozing can be stopped by gauze pressure for a minute or two. Suturing of the sheath of the vessel is recommended, as it makes a barrier to sepsis. The author hopes the lateral implantation of one artery in another will be found possible.

Catgut as a Ligature and Suture Material.—Hugh Cabot writes that as a general rule, catgut should be used in sizes as small as will do the work required in any given case, as the use of too large sizes is one cause of unsatisfactory results, also that care in tying and cutting catgut ligatures is essential to safety. It will generally be admitted that where vessels of large size or large masses of tissue are concerned, the softening which takes place in catgut when in contact with moist tissues will make its hold less secure than that of silk. The fault under these circumstances and the liability to secondary hemorrhage belong not always to the material, but to the manner in which it is applied. The dangers of trusting to two knots instead of three, and of cutting the ends too short, have not been sufficiently recognized. Many surgeons prefer to use large sizes instead of small ones, on the ground that the latter are not strong enough. This seems to imply that too great tension is put on the sutures. No suture tied under much tension can be depended upon to maintain nice approximation, for it will inevitably cut out until this tension is relieved. This process of cutting involves a certain amount of necrosis of tissue and consequent wound infection.

Journal of American Medical Association, March 29, 1902.

The Use of the Gall Bladder to Restore a Prolapsed Liver.—A. F. Jonas finds this a practicable procedure, the idea being to use the viscus as a suspensory ligament. In two instances it was sutured in the uppermost part of the wound, snugly against the costal arch, the sutures passing through the gall bladder wall, parietal peritoneum and muscles. Jonas concludes as follows: (1) The cause of hepatoptosis consists in a modification of one or more of its normal supports, or in an increase in the size and weight of the liver; (2) It is impossible for the liver to descend without producing a descent of the hollow abdominal viscera; (3) The utilization of the gall-bladder as a suspensory ligament, to maintain and hold in its normal position a prolapsed liver, together with certain other abdominal organs, seems practicable.

End-to-End Approximation of the Broad Ligaments and Other Points of Technique in Abdominal Hysterectomy.—E. C. Dudley enumerates the advantages of the mode of approximation referred to in the title as follows: (1) The broad ligaments when thus approximated take the place, in an anatomical sense, of the excised uterus, and form a pouch posteriorly that corresponds to the *cul de sac* of Douglas and anteriorly a depression that answers for the uterovesical pouch; (2) The broad ligaments, if brought together end to end, give support to the rectum, vagina, bladder and other parts of the pelvic floor, and in so doing prevent the descent of those parts—a descent which so commonly results from hysterectomies as ordinarily performed; (3) The broad ligaments when brought together by end-to-end approximation, are interposed between the bladder and rectum and thus prevent the intimate union of these two viscera—a union that would leave a very thin wall between them through which infection might pass from one to the other; (4) The operation is more quickly and easily performed by this method than by that of side-to-side union of the ligaments.

The Prostate.—From an extended study of the effects of prostatic enlargement, J. B. Murphy comes to the following conclusions: (1) From the clinical reports and experiences it seems evident that in extreme cases prostatectomy is the operation of election; (2) It appears evident that in the hands of good, far-seeing, informed practitioners, few cases will now be allowed to progress to this extreme condition before radical means are resorted to for permanent relief; (3) Continued use of the catheter is a menace to life, not to mention its discomfort, no matter how favorable the conditions for its performance. The patients all sooner or later suffer from cystitis and its sequelæ; (4) Prostatectomy gives the best permanent result, and is fraught with very little more danger than prostatotomy; (5) Suprapubic prostatectomy should be limited to exceptional cases of enormous intravesical enlargements of the prostate. It appears to endanger the sphincter control more than the perineal operation. It is more unsanitary, and the work is more difficult and distant from the operator; (6) The perineal is the most direct and least bloody route. It admits of a very large opening and permits the prostate to be drawn quite into the open before it is attacked. It gives the greatest security against injury to the bladder wall and least liability to disturbance of the internal sphincter. It endangers the rectum least and affords the best drainage; (7) It can be best performed through a Y-shaped incision, with a Sims' speculum for a posterior retractor. The prostate is drawn out easily with sharp hook retractors, and best separated from the bladder from behind forward. The operation should never be performed in the dark, i.e., through a small incision; (8) It should always be an intracapsular enucleation *en masse*, allowing the anterior isthmus to remain. The hemostasis may be secured with forceps or a packing of subiodide of bismuth (not iodoform) gauze. The permanent catheter should not be introduced until the perineal drain is removed; (9) The patient should be kept in a semi-sitting position for seventy-two hours after the operation, and should be out of bed by the fifth day; (10) Anesthesia is *sub judice*. Phosphate of soda should be given to keep the urine acid and urotropin as an antiseptic. Water should be taken freely throughout.

The Philadelphia Medical Journal, March 29, 1902

The Supraorbital Reflex—An Explanatory Note.—D. J. McCarthy states that the upper part of the face is richly supplied with sensory nerve filaments from the fifth nerve, all of which are accessible to mechanical or sensory irritation. A careful study of the reflexes in this area will show that there are several independent and distinct reflexes, as follows: (1) A pure sensori-motor reflex, in the nature of a skin-muscle reflex, elicited from the supraorbital distribution exclusively; (2) A periosteal reflex may be obtained when there is an excited condition of the reflexes, by irritation (percussion) over the malar arch or the periosteum of the nose (v. Bechterew, Overend); (3) The corneal and conjunctival reflexes may be obtained by irritation of these structures; (4) The corneomandibular reflex of v. Solder is a lateral movement of the lower jaw, produced by irritation of the cornea.

A Case of Herpes Zoster Ophthalmicus.—W. S. Durand reports the case of a man aged fifty-two years. For about three weeks prior to the eruption of vesicles there was extreme pain in the region of distribution of the left cervical plexus and through the region of the eruption, although there was no sign of eruption in the cervical region. The monolateral distribution of the eruption was perfect. There was a vesicle in the median line on the summit or root of the nose, and two or three larger ones reaching just to the middle of the forehead and along the sagittal suture. The vesicular eruption was profuse, reaching almost to the left ear, the ear and region of distribution of left cervical plexus remaining extremely painful. When first seen the left eye was completely closed. The writer dropped a drop of a solution of adrenal in chloride, 1 to 1000, in normal sodium chloride solution, with 5 per cent. chloretone into the eye. The drop was repeated in about a minute, and in about another minute the patient could open the eye which had by this time completely blanched. The use of the solution was continued, generally diluted, 1 to 10,000, four or five times a day. The 1 to 1000 solution was also freely applied with a camel's hair brush over the entire region of the eruption two or three times a day when pain returned. The results of this treatment, combined with the necessary constitutional treatment, were most gratifying. The sight of the eye was as good as originally.

New York Medical Journal, March 29, 1902

The Radical Cure of Hydrocele by Minute (Two Minim) Injections of Carbolic Acid.—This plan of treatment is highly commended by W. B. Coley and P. A. Satterwhite, who review the literature of the subject and report several personal cases. At the Hospital for Ruptured and Crippled in New York City the routine treatment in infants and children consists in simple daily applications of equal parts of tincture of iodine and tincture of belladonna. Long experience with this method has convinced the authors that it has some effect in hastening the absorption of the fluid, although doubtless spontaneous cure would result without any application. Occasionally, when the hydrocele is very large, the fluid is aspirated and the tunica irritated by the point of the trocar. This is not done more than three or four times in the course of a year. Hydrocele in the adult, however, is a condition that requires more serious consideration. Formerly ten minim injections of carbolic were used, but experience has shown that practically as good results can be obtained with two-minim doses. This small amount the authors believe to be absolutely free from all risks.

A Prostatectomy Forceps.—R. Guiteras figures the instrument thus named, and states the following as his procedure in cutting through the floor of the urethra: (1) Perineal urethrotomy; (2) Dilatation of the prostatic urethra by means of the Kollman dilator; then with the forefinger and sometimes with the thumb; then, after inserting the forefinger of the left hand into the rectum and placing it at the apex of the prostate, the operator passes a thin pair of sharp-pointed curved scissors into the perineal incision until their points have come in contact with the prostatic urethra. He then either cuts through the floor or passes the points of the scissors through the mucosa and capsule at this point, and spreads open the blades so as to tear the tissue at this point. It is now easy to insert the forefinger of one hand, usually the left, into this space, and, having made a few sweeps of the forefinger around the apex of the gland, the forceps can be pushed up alongside the finger and can grasp the lobe. Gentle traction is then exerted by the hand holding the forceps, while the forefinger of the other hand proceeds to sweep around between the gland and its capsule until the former has been loosened and removed. A similar enucleation is then performed on the other lobe, and if any middle lobe is present it can be grasped by other forceps and removed. In this way the prostatic urethra is injured less extensively than if it is split down vertically through the middle of its floor by a knife inserted into it. Besides, there is not so much danger of wounding the rectum by this method. It is important to remove the lateral lobes separately, even if the whole prostate can be removed *en masse;* for otherwise the entire prostatic urethra would come away with it.

The Obesity of Adolescence.—Heinrich Stern says that most cases of transitory obesity in adolescents run an uneventful course. Anorexia, chlorosis, constipation, headache, and dull pains in back and loins are often present; a sense of rigidity in the joints and sacro-lumbar region, giving rise to ungraceful and awkward motions, is not uncommon; circulatory disturbances, synchronously produced with transitory obesity, or appearing during the course of the latter, are not very frequent and seem comparatively slight; however, pre-existing anomalies of the circulatory apparatus may occasionally become decidedly aggravated after abnormal fat deposition. In severe cases we may meet with pronounced anæmia or leucocytosis; and, in rare instances, with vertigo and cardiac dyspnœa.

The dietetic treatment alone will suffice in most instances. In other cases an increased amount of exercise, gymnastics of the lungs, massage, hydrotherapeutic and other measures, must be resorted to in addition to the former. Medicines should be administered, if at all, only for the accompanying disorders, and never for the reduction of metabolic obesity during adolescence. In cases of transitory obesity demanding treatment, dietetic restrictions are not only superfluous in the vast majority of cases, but often effect lasting injury on the youthful organism. Our therapeutic efforts in such instances should be directed rather to the complications and concomitant disturbances than to the obese condition itself. The latter, if extreme and giving cause for alarm, may be treated by preparations of thyreoid. A safe form of administering thyreoid substance is this: Arsenous acid, 1-60 grain; adonidin, 1-12 grain; thyreoid gland, dry powder, 2 grains.

American Medicine, March 29, 1902.

Movable Kidney; with Possible Explanation of Failure in Some Cases to Relieve Symptoms by Nephrorrhaphy.—George H. Mallett believes that in cases of movable kidney, when an operation is indicated and the symptoms persist after operation, in most instances the kidney has been fixed in a malposition, and when the operation has been performed by the method which is most frequently used at present, it has been rotated outward on its vertical axis. He emphasizes the fact that when performing nephrorrhaphy, fixation of the kidney alone is not all that is required, but care should be exercised that the circulation of the ureter and vessels is not interfered with, since the possibility of these occurrences is not so remote as has been supposed.

Sand Filtration in Relation to Disease.—James M. Anders declares that the deleterious and devitalizing effect of imbibing impure water, especially when bacterially contaminated, upon the general health of the community is practically inconceivable. It lowers the resistance to the large class of infectious diseases, and it is productive of much suffering, caused by the habitually depressed and weakened systemic condition due to its ingestion. Much inconvenience and ill-health, caused by impure drinking water, originate primarily from the digestive tract, and are due to gastric and intestinal disturbances. Impure water is often used for a long time without causing any specific disease, in those who have grown accustomed to drink it, while a stranger drinking it for the first time is quickly attacked by the specific malady, the germs of which have been introduced into the system by the water. The writer believes in the efficiency of sand filtration as a practical means of minimizing the prevalence of diseases produced by polluted drinking water. Although the primary cost of slow sand filtration is greater, and although it requires more space, still it is superior to mechanical filtration. The latter is more expensive to operate and demands the utmost care. Sand filtration is also a natural process.

The Treatment of Suppuration in the Uterine Appendages.—Charles P. Noble gives the results of his experience with 200 cases of pelvic suppuration which have been operated upon. The advance made in this work during the last fourteen years has reduced the mortality from more than 16 per cent. in the first half of this period to less than 5 per cent. in the second half. This improvement has been obtained by: (1) Abandoning abdominal section in the treatment of pyosalpinx and abscess of the ovary when complicated by intraperitoneal abscess, and by substituting direct incision and drainage in this group of cases, and also for recent cases of pelvic suppuration of puerperal origin; (2) By substituting hysterectomy for oophorosalpingectomy for the removal of bilateral suppuration in the uterine appendages. The results of the improved technic are excellent. Ventral hernias, pedicle abscesses and troublesome intraperitoneal adhesions have become very rare. Free incision and drainage in cases of suppuration of the uterine appendages complicated by intraperitoneal abscess has proven to be a most valuable life-saving measure. It has proven also to be a most conservative measure in the conservation of the sexual organs. Direct incision and drainage finds its best indication in: (1) Puerperal phlegmon; (2) Puerperal ovarian abscess, intraperitoneal abscess and pyosalpinx; (3) In complicated cases of pelvic suppuration, of whatever origin, in which the pus is not contained within the ovary and tube. The value of direct incision is most manifest in the worst class of cases, and in which the abdominal section gives its worst results.

Medical News, March 29, 1902.

The Detection of Typhoid Bacilli in the Fæces as a Diagnostic Test of Typhoid Fever, and a Comparison of This Test with the Widal Reaction.—Henry A. Higley concludes that: (1) During the second week of typhoid fever, when technical aids are of the greatest value to the practitioner, isolation of typhoid bacilli from the fæces gives slightly better results than does the Widal test. These two methods used in combination, when the tests are carefully and persistently made, render material aid in the diagnosis of this disease previous to the appearance of distinctive clinical symptoms; (2) By the use of the Hiss isolation method, especially with the substitution of the new platinum medium, the detection and isolation of typhoid bacilli are, to one familiar with bacteriological methods, simple, reliable, and practical.

Remarks upon Some Experiences with the Widal Reaction.—E. Libman believes that: (1) A positive Widal reaction always means that typhoid fever is or has been present; (2) Partial reactions are to be absolutely ignored; (3) A negative reaction does not exclude the existence of typhoid fever. It occurs under any of the following conditions: (*a*) The reaction may have already disappeared; (*b*) The reaction may only appear later; (*c*) The culture may be at fault; (*d*) The case is clinically one of typhoid fever, and there may never be a positive reaction; (*e*) The disease is not typhoid fever. A negative reaction may occur if the patient is suffering from an infection by a paracolon bacillus, and still, for the practitioner, the case is identical with one of typhoid fever. Again, a positive reaction may occur when the case is clinically not one of typhoid fever and [illegible] the autopsy may show the presence of the typhoid bacillus in some part of the body, or it may be found during life in the urine, [illegible] rose spots, blood or some complicating lesion. (4) Theoretically, the Widal reaction is of the greatest value in establishing the presence of infection by the typhoid organism in certain cases and in assisting in identifying the typhoid bacillus. It is of great practical use, but it is not so valuable as could be wished. In many cases, however, it can alone establish the diagnosis. This is especially true in the atypical cases in which pneumonia or meningeal symptoms usher in the disease.

The Lancet, March 22, 1902.

The Etiology of Typhoid Fever and Its Prevention.—In the first Milroy lecture W. H. Corfield traces the development of the history of typhoid during the last thirty-five years gradually leading up to the discovery of the bacillus typhosus. Frequent references are made to the literature of the subject and the lecture is of especial interest from an historical point of view.

A Case of Primary Hemorrhage into the Fourth Ventricle.—H. W. Reynolds reports this rare case. His patient was a woman of thirty-five years admitted to hospital with renal disease, hydrothorax and edema of the legs. One day about a month later, she suddenly developed bilateral paralysis of the lips, tongue and pharynx, so that she could not articulate properly, protrude her tongue or swallow except with difficulty, while saliva dribbled from the mouth. There was no headache or any other premonitory symptom except, perhaps, the vomiting, and consciousness was perfect throughout. There was no paralysis of the limbs or ocular muscles. The most marked feature was the defect of articulation which really drew attention to the condition, the defect being inability to pronounce the labials. She died three days later and the autopsy showed a hemorrhage into an otherwise healthy brain. The Sylvian iter was free from clot, as were the third and lateral ventricles, showing the hemorrhage to be primarily of the fourth ventricle. It was seen that the blood had plowed its way into the posterior part of the pons and medulla where it would involve the nuclei of the cranial nerves, but not the pyramidal tracts. Judging from the symptoms, the nuclei affected were those of the seventh, tenth, and twelfth, the sixth being unaffected. The sudden death may perhaps have been due to a second hemorrhage involving the respiratory center.

Electric Shocks at 700 Volts.—A. P. Trotter says that the dangers of electric shocks at 500 volts have been much misunderstood, greatly exaggerated, and little investigated. The pressure of 500 volts has been deliberately chosen by electrical engineers, because it is not dangerous under ordinary conditions. The conditions under which serious shocks are not produced by 500 volts are discussed in the paper, and it is safe to assume that all shocks more serious than those which are recorded are dangerous. Dry wood and dry boots without large nails offer so great resistance to electric current, that it is perfectly safe to touch a trolley wire while standing on a dry tram-car, or even while standing on the ground or on the rails. Wet weather makes a considerable difference, but boots must be very wet to allow enough current to pass to produce a severe shock. Men engaged in electric traction work receive many slight electric shocks at 500 volts, and they might avoid most of them by taking more care. Dry clothing offers so great a resistance that no shock can be transmitted through it. The peculiar conditions under which shocks at 500 volts have caused death are discussed and are shown to be very exceptional. Experiments have been made on some thirty persons, including twelve women and six children, and it is proposed to make other experiments. With sound dry boots hardly anybody can feel a shock when standing on the live rail of an electric railway with one foot and a running rail with the other. With damp or wet boots a shock is felt, but neither the sensation nor the degree of wetness of the boots can be measured accurately. It is not possible to receive a shock by sitting or lying on a live rail so long as the clothes are dry and continuous, that is to say, so long as the live metal is not touched by the bare skin.

The Pulmonary Circulation, More Particularly in Relationship to Variation in Cardiac Activity.—In a lecture upon this subject T. G. Brodie mentions, among other topics, the effect of suprarenal extract upon the heart. He notes from his experiments that this remedy causes a profound influence on the heart, the rate of which is increased while output is nearly doubled. The effect on the heart, however, is complicated if the vagi be undivided by a marked inhibition of the heart, occurring mainly during the period of heightened aortic pressure. The effect of suprarenal extract upon the blood volume of the lungs is to cause first a small diminution in volume soon followed by a marked increase, which persists during and for a short time after the rise in aortic pressure. Thus the main effect is to produce a distinct congestion of the lungs. The effect upon the pulmonary blood pressure is a rise to nearly double its original amount, commencing with but lasting rather longer than the rise in aortic pressure. The left auricle pressure at first falls, but rises rapidly when the aortic pressure has reached a high point. The effect upon the right auricle pressure is a gradual and slight rise following the rise in aortic pressure. From these results it is concluded that the effects are mainly due to the action of the peripheral bloodvessels in causing the large rise in aortic pressure. They are, however, complicated by the action upon the heart. The increased output observed at first explains the preliminary diminution in volume of the lungs and the rise in pulmonary pressure. The later effects are due to the rise in the aortic pressure and the consequent inability of the left ventricle to empty itself. The more reflex inhibition there is produced, the more marked, as a rule, is the pulmonary congestion. These facts have an important bearing upon the question whether suprarenal extract can be advantageously used in hemorrhage from the lungs. Certainly in the doses which Brodie has employed, and with intravenous injection, his experiments strongly contraindicate its employment for such a purpose.

British Medical Journal, March 22, 1902.

Carcinoma and Malaria.—Albert R. Cook declares that in his experience in Central Africa he has had over 1,000 in-patients and about 16,000 out-patients under treatment the last year. Among this number were some 1,300 cases of malaria, while malignant cases were not rare. He believes that malaria is no bar to the occurrence of carcinoma and he protests against inoculating cases of carcinoma with the protozoon of tertian fever as a preventive of carcinoma.

A New Diagnostic Point in Typhoid Fever.—Heneage Gibbes believes that the method of showing the eruption of typhoid fever by photography, before it can be either seen or felt, will prove of great value to the clinician. The best plan is to use orthochromatic plates, and make a number of exposures as quickly as possible. The directions are as follows: Cover the face and head with a light shawl and remove the coverings from the abdominal region, moisten a small bit of printed matter and stick it to the skin to get the focus, have an assistant throw as much light as possible on the part, with a mirror. Out of six exposures of varying length, one or two should show the rash. Great care is required in developing the plate. Over-exposure must be avoided. Hydrokinon or paramol give good negatives. The writer believes that this method will prove of value in atypical cases.

Pince-nez in Ophthalmic Practice.—Robert D. Joyce has observed a number of persons wearing pince-nez who complained of epiphora or flowing of tears. In some cases two pairs of glasses were used, pince-nez and ordinary spectacles, and only when the former were worn was the trouble noticed. At first the writer thought the irritation was caused by not wearing the glasses exactly straight, but he discovered later an entirely different cause for the trouble. It is caused by the compressing force of the pince-nez dragging on the tissues at each side of the nose to such an extent that the lower lid is actually pulled away out of position and is no longer in close contact with the bulbar conjunctiva. Even a small amount of eversion is sufficient to cause the epiphora. The surgeon should see the frame on the patient before the lenses are fitted into it, and assure himself that the spring is as weak as is compatible with steadiness. In some cases the pince-nez cannot be fitted without causing this ectropion.

Notes on Adrenalin Chloride Solution in Ophthalmic Practice.—George A. Ferdinands states that when adrenalin chloride solution is instilled into the healthy eye (solution 1 in 1,000) it first causes a slight smarting, and within a few minutes a blanching of the conjunctiva, which is best marked at the caruncle. The blanching reaches its maximum within five minutes. The solution is non-irritating and causes no dilatation of the pupil. It does not render the conjunctiva or cornea insensitive to any extent. It has no effect on accomodation. It gives relief in a few minutes when applied to an inflamed conjunctival sac. It is particularly valuable in iritis and relieves photophobia. It assists the absorption of subcorneal deposits and thus improves vision. In tenotomy and advancement of the rectus the previous instillation of this solution helps to control the hemorrhage. The writer has never observed any toxic effect. In cases in which the nutrition of the tissues is at fault, the solution of adrenalin chloride is contraindicated.

Deutsche medicinische Wochenschrift, March 6, 1902.

Tonic Contractions of the Stomach.—I. Boas says that tonic contractions of the fundus of the stomach may be divided into three classes according to their intensity and duration: (1) Slight contractions, which are only with difficulty felt by the hand and involve but a portion of the fundus. They last but a few seconds and are not perceptible to the patient. As a rule, they are accompanied by no gurgling sound; (2) Moderate contractions which are plainly felt by the hand and are generally visible to the examiner. They are of but short duration and are always followed by a gurgling sound. The patient complains of slight pain during the continuance of the contraction; (3) Powerful contractions which produce a movement of the entire anterior abdominal wall and are accompanied by loud gurgling sounds and pronounced pain. They are of much longer duration than either slight or moderate contractions. Tonic contractions of the stomach are only observed when food is present in the organ. They are diagnostic of pyloric stenosis and vary in intensity directly with the degree of such stenosis. Pyloric stenosis may be nervous in origin (spasm of the pylorus) or it may be due to cicatricial narrowing resulting from carcinoma, ulcer, etc. The varieties of tonic contractions of the fundus do not suffice for a diagnosis of the cause of the pyloric stenosis, but only for an estimation of its degree. Thus powerful contractions may accompany spasm of the pylorus, while carcinoma may only cause slight contractions. However, when tonic contractions are present it is certain that pyloric stenosis exists and further measures should be instituted to ascertain its cause. Three cases are related in illustration of the above principles.

Berliner klinische Wochenschrift, March 10, 1902.

Alcohol as a Hand Disinfectant.—R. Schaeffer reports the results of his experimental researches concerning alcohol as a hand disinfectant or sterilizer. The hot water-alcohol method of hand disinfection is usually conducted in the following manner: The hands are thoroughly washed with soap and a sterile hand-brush in water as hot as can be borne for from five to ten minutes, after which they are soaked for five minutes in absolute alcohol. It has been thought by some that the hot water washing in itself is the most important part of the process. In Schaeffer's first series of experiments the hands were thus washed successively five times in five separate portions of water, a new brush and soap being used each time. The entire washing occupied thirty minutes. Plate cultures were then made from each portion of water, and it was found that the last portion contained one hundred and twenty micro-organisms to the cubic centimeter. The first portion contained seven hundred bacteria to the cubic centimeter. In the second series of experiments the hands were washed in the prescribed manner and dried with a sterile cloth. Plate cultures were then made from the hand-scrapings, and it was found that on the average five hundred micro-organisms to the cubic centimeter were present. It is thus shown that after such washing the hands are by no means sterile. In the third series of experiments, in addition to the washing the hands were soaked in alcohol for five minutes and then placed in sterile water for fifteen minutes. Cultures were then made from the hands, and it was found that on the average only three micro-organisms per plate were present. Since alcohol in the manner used is not a powerful bactericide, the author thinks that its chief action is one of mechanical purification although its property of hardening the skin undoubtedly plays a certain part in the process. In a final series of experiments the efficiency of the hot water-alcohol method was compared with that of other procedures, and it was found it gave much better results than any of these. The method of Mikulicz is fairly efficient, as following its use only twenty-five bacteria per plate were present. None of the so-called antiseptics are efficient. One hundred and fifty micro-organisms per plate were present after the use of bichloride (1-1000), seventy-six after lysol ($1\frac{3}{4}$ per cent.), five hundred after chinosol (6 per cent.) and fifteen hundred after lysoform ($3\frac{1}{3}$ per cent). In cases of necessity the washing with the hot water and soap may be reduced to five minutes, but the soaking in alcohol must always last five minutes and can never with safety be reduced below this time. A final washing with bichloride (1-1000) would undoubtedly make the process still more effectual.

The Hydrotherapy of Pulmonary Tuberculosis.—S. Munter draws attention to the fact that the physiological processes of the body are accelerated by thermic irritations so long as such irritations are confined within suitable limits. In hydrotherapy water is used as the source of this thermic irritation. In pulmonary tuberculosis suitable hydrotherapy is followed by an increase in appetite and in the assimilation of food, and by an improvement in the general condition, with an amelioration of the special symptoms. As long as the normal temperature of the body is not altered, cold increases oxidation and heat decreases it. The reverse is the case, however, if abnormal bodily temperatures are present. Since in pulmonary tuberculosis, on account of the sensitive metabolism present, the bodily temperature is very easily changed, it is necessary in the hydrotherapy of this disease to employ methods which produce neither subnormal nor hypernormal bodily temperatures, since the former in pathological conditions reduce the functional activity of the various organs, while the latter markedly increase oxidation, so that the weight and strength are more or less rapidly reduced. In order to avoid these consequences, the following method should be employed: (1) The surface temperature of the body should be increased by the application of heat. Thus the superficial capillaries are dilated, and the heat which is added is concentrated on the surface of the body; (2) Cold is applied, by means of which the added heat is withdrawn and the capillaries contracted; (3) A reaction is produced by friction, which restores the capillaries to their previous condition. In this manner the entire system is brought under the tonic influence of the cold without producing alterations *in toto* of the body temperature. Cases of pulmonary tuberculosis in which there is no mixed infection are treated most successfully by the use of the more pronounced measures. Cases of mixed infection should be treated by the milder methods, since marked fever is here present, and the effect of pronounced thermic irritations is unfavorable. Local hydrotherapy is very useful in the treatment of specific lung symptoms, such as pain, cough, and dyspnœa, and, furthermore, in improving the cardiac action, which, in turn, cannot fail to increase the functional activity of the entire body. The principles of this local treatment are the prolonged application of heat, the short application of cold, and the production of a good reaction. Atonic stomach and intestinal disorders, which frequently accompany pulmonary tuberculosis, are usually successfully treated by the use of such local hydrotherapy applied to the abdomen. Many cases of pulmonary tuberculosis show marked improvement by the use of the following method: The body is sponged from two to three minutes with water at 40°C.; the temperature of the water is then suddenly changed to 16°-20°C., and the sponging continued for 20-40 seconds; finally, a proper reaction is produced by friction. It is important to remember that in all hydrotherapeutic methods the change from heat to cold should be sudden and pronounced. Only in this manner can the full tonic effect be produced and serious consequences avoided. A further benefit of hydrotherapy in pulmonary tuberculosis is to be found in the fact that patients thus treated rarely contract the colds to which phthisical patients are extremely susceptible. Complications are thus frequently avoided. Some have thought that patients so treated are especially prone to hemoptysis. Extended observation shows that such is not the case. It should be remembered that cases of pure tubercular infection are the most suitable for hydrotherapy, and that when mixed infection is present great care should be exercised in the use of the so-called "water treatment."

French and Italian Journals.

Pulsatile Palpebral Tumor.—Lagrange has a patient who, since the age of fifteen, has had a pulsatile palpebral tumor showing an exacerbation of symptoms at each menstrual epoch. During the last year the phenomena of irido-choroiditis have appeared, but they have yielded to treatment (iridectomy). The inflammation has disappeared, but the arterial vessels persist. The case is interesting by reason of the rarity of arterial varices; because these varices have determined an ocular inflammation; and because the affection, which began with the appearance of the menses, is aggravated at each menstrual period.—*Journal de Médecine de Bordeaux*, March 9, 1902.

The Treatment of Rheumatism by Lemon Juice.—Desplats reviews his experience with this method. The first case that he treated was that of a young girl, who had been attacked primarily with angina, probably grippal. Following this attack she had suffered from acute articular rheumatism. She had been temporarily relieved by salicylate of soda, and then her condition became stationary. At this time the administration of lemon juice was begun. In about eight days there was a marked improvement. At the end of fifteen days the patient was entirely cured and left the hospital. The second case was treated with salicylates for three weeks without much success, but as soon as the lemon juice was begun the results were the same as in the first case. In fifteen days there was a complete cure. The first case in the second series of cases was treated from the beginning with lemon juice. The results were en-emerging, but at the time of the report it was only the sixth day of treatment. Another case, a chronic rheumatic treated by this method, was relieved of her severe pain. The treatment is begun by giving two [illegible], the number being increased to four, then to six, and so on till the patient shows a marked improvement, and then the dose is kept uniform at what is considered the effective point.—Journal des Sciences Médicales de Lille, March 1, 1902.

Spasm of the Pylorus Mistaken for a Tumor, Operation, Cure.—[illegible] reports the case of a woman of fifty-eight years, who presented all the symptoms of a tumor of the pyloric region of pyloric stenosis, [illegible] and epigastric pain [illegible]. The diagnosis was confirmed by several physicians and surgeons. Nevertheless, the woman had never had hematemesis and she did not present the appearance of tumor of the epigastric region. The operation revealed a condition of simple pyloric spasm (the stomach contracted with great readiness under the fingers of the operator), this being due, probably, to the presence at the level of the pylorus of a small indurated area about the size of a small nut. This was excised, and since the operation the patient has not shown the least gastric symptom.—*La Presse Médicale*, March 1, 1902.

The Treatment of Wounds by Alcohol Acidified by Acetic Acid.—Luigi de Gaetano holds that in the treatment of wounds healing by first intention the method is a very great preventive of infection. The suture material should soak in the solution (20 drops of acetic acid to 100 grammes of ordinary alcohol) during the operation, and be dried by sterilized gauze before using. The needles should be pushed from beneath upwards and outwards. As soon as the operation is completed the surface of the wound is to be washed with the acidified alcohol, and dabbed with gauze soaked in the solution. The first layer of gauze used in the dressing is also to be soaked in it. Two days after the operation the dressing is removed and the surface of the wound washed and dressed as before. On the fifth day the wound is washed with the alcohol, the stitches removed, and the moist dressing again applied.—*La Riforma Medica, March* 4, 1902.

Delirium in Croupous Pneumonia.—A. Brancati concludes that delirium is fairly frequent in pneumonia, and, as in all acute infective processes, constitutes a grave complication. Certain predisposing conditions—as alcoholism, syphilis, malaria, auto-intoxications, excitability of the nervous system and extension of the pneumonic process—act in conjunction with the influence of the bacterial toxin, to produce this delirium. It is observed especially at the acme of the disease, because that is the period of greatest activity of the micro-organism in the production of toxic substances. It also, usually, coincides with a high temperature, the cases of delirium with a low temperature being due to incomplete elimination of the toxins and a lack of equilibrium in the cerebral circulation from diminished febrile stimulation.—*La Riforma Medica*, March 5, 6, and 7, 1902.

Extract of Suprarenal and Adrenal Glands in Nasal Surgery.—Carlo Biaggi, in operations on the nasal septum or on the turbinated bones, applies a small tampan, soaked in a 50 per cent. glycerin solution of the extract of suprarenal gland, and close to it another tampon, soaked in a cocaine solution. The mucous membrane becomes very pale and shrunken, and no loss of blood occurs. After the operation another tampon, steeped in the solution, is laid along the line of incision to prevent hemorrhage. The extract of adrenal gland has a powerful vaso-constrictor action, and can be applied in a 1 to 1000 solution, by simply painting it on the mucosa with a brush, without the necessity of prolonged contact with a tampon. Followed by an application of cocaine, the operation can be performed without the slightest pain or the least hemorrhage.—[illegible], February, 1902.

A Case of Cataract Due to Lightning.—Francesco [illegible] reports the case of a soldier who was struck by lightning and rendered unconscious for awhile. After recovery he felt perfectly well, with the exception of a burning and redness in the left eye. The discomfort persisting, he entered the hospital a week after the accident, where a diagnosis was made of conjunctivitis. After treatment of boric acid and rest for eighteen days the patient was discharged cured. Gradually, however, he noticed diminished vision, first in the left and then in the right eye, and at the present time cataract of both eyes is very evident. It is not to be denied that this is the effect of the lightning. Some authorities consider the condition due to shock, others to the heat or to the chemical action (electrolytic) developed by the electric spark. By electric shocks to animals Hess has determined mortification of the capsular epithelium with resulting cataract.—[illegible], February [illegible], 1902.

Sudden Death Due to Dyspepsia.—[illegible] states that dyspepsia is an important factor among the causes of sudden death. The physiologists have offered the explanation for sudden death coming after a shock to the epigastrium, that it is due to an excitation of the nervous system. In legal medicine a number of such cases are reported under the term inhibition. A pathological condition of the stomach often plays the same rôle. A proof of this is the frequency of sudden deaths soon after eating. The author reports a case of sudden death due to excitation of the nervous filaments of the gastric mucosa. He also cites cases of sudden death in individuals without objective lesions of the heart or vessels, but who are suffering from gastric affections. Diet will often prevent these accidents. If they occur, rhythmic traction of the tongue and flagellation will help to combat them. Sudden death may also be due to the condition of the respiratory [illegible].—*La Tribune Médicale*, March [illegible], 1902.

Injections of Durand's Fluid into the Pulmonary Substance.—G. [illegible] and S. [illegible] have found in their experiments on rabbits with Durand's iodo-iodized solution that the weight of the animal is increased, which demonstrates proof of improvement in the general nutritive condition. Were the same result obtainable in a tubercular patient, it would seem that his organism would be placed in a better condition to resist the invasion of the bacillus. Hyperemia and the presence of leucocytes in the injected lung authorize the supposition that the reactionary inflammatory process induced by the Durand solution may neutralize the destructive activity of the Koch bacillus and destroy the virulence of its toxin. In conclusion, the authors assert that injections of this solution can be made with impunity into the lung substance under proper aseptic and antiseptic precautions, and that even larger doses will cause no inconvenience. They hope later to report more positive results obtained by the remedy on the human lungs.—*Il Policlinico*, February, 1902.

Lesions Produced in Various Organs by Experimental Intoxication with Typhoid Toxins.—Luigi [illegible] describes his experimental methods in detail. Myeloid degeneration of the spleen occurred in guinea pigs, but, strangely enough, in rabbits it was absent, and there was an increase in the pre-existing mononucleated cells. In the liver fatty degeneration was most diffuse and abundant in rabbits, while in guinea pigs there was cloudy swelling and plasmolyses. In the kidneys the lesions were not at all times of equal gravity; in some cases there was a true nephritis and not merely a degeneration, as occurs in nearly all experimental intoxications. A phenomenon found in all the organs and tissues is the infiltration of leucocytes, this being especially marked in the liver. The mononucleated cells are in the greatest abundance. The conclusion reached by the author is that the toxic substances derived from the typhoid bacillus prepared by his special method have produced in the animals inoculated with it lesions localized more especially in the lymphatic apparatus, but involving glandular parenchyma as well, and producing important and characteristic lesions.—*Giornale Internazionale delle Scienze Mediche*, February 28, 1902.

Black Water Fever and Quinine.—Leonardo Cega de Celio reports a case of black-water fever which is interesting in many respects. The patient was suddenly taken sick with what was apparently a malarial attack, and took, of his own accord, a small dose of quinine. On the following day his fever increased and hematuria set in. A physician was called, who prescribed euchinin. No benefit was derived therefrom, and on the following day de Celio saw the patient. At this time the temperature was 39.5° C., pulse 130. Hematria was still present. No malarial organisms were found in the blood. Euchinin was continued, and a small dose of quinine given hypodermically. This was repeated on the following day, but the patient rapidly grew worse and died in a comatose condition. Previous examination had eliminated disease of heart or lungs, but the spleen and liver were found enlarged. The author thinks that the diagnosis lay between pernicious malaria and black-water fever, due to the quinine taken by the patient himself. In such cases it is well nigh impossible to make a correct diagnosis and direct treatment accordingly. In black-water fever, due to quinine, euchinin, as a rule, gives prompt relief. Nevertheless, in this case it was without avail.—*Wiener klinische Rundschau*, February 23, 1902.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held March 18, 1902.

JAMES K. CROOK, M.D., CHAIRMAN.

Symposium on Acute Articular Rheumatism.—This was the special subject for the evening.

Remarks on the Pathogenesis.—Dr. HEINRICH STERN read this paper. He said that the hypothesis of the microbic origin could not be said to be founded on clinical facts. Regarding the old theory of acidæmia, the speaker said that he had estimated the blood alkalinity in a number of cases and had found the average to be 379, whereas from 1,000 determinations in normal blood he had found the alkalescence to vary between 300 and 500. He concluded that the acids that had been detected in the transudate in some uncomplicated cases of rheumatism owed their presence to some other factor, probably a ferment. The urine in acute articular rheumatism does not ordinarily exhibit a very high degree of acidity. It was commonly spoken of as "highly acid," but such a term was inaccurate and misleading. He had resorted to acidimetry in the examination of twenty-eight specimens taken from five males in the first week of acute articular rheumatism, and had found the highest and lowest results to be 0.66 and 0.29 respectively. This did not indicate a great deviation from the normal, as the average for normal urine was 0.43. If the urinary chlorides were found to be considerably increased, the disease could hardly be rheumatic fever. In acute rheumatism the urinary chlorides would be found decidedly reduced, and this occurred in only one other disease, pneumonia. In the latter it was most marked in the stage of congestion, but in many cases it was not a striking feature.

The Symptomatology and Diagnosis.—Dr. LEONARD WEBER read this paper. He said that, although there might be some antecedent malaise, the onset was sudden and rapid, the disease often being fully developed within twenty-four hours, with a pulse of 100 or more and a temperature of 102° to 104° F. The urine would be found acid, and there would be free perspiration. He saw more cases of acute rheumatism in the spring and summer than at any other time. Monoarticular rheumatism was very rare. Occasionally the vertebral column was affected. The effusion sometimes extended to the neighboring muscles and tendons. In very well marked cases anæmia developed rapidly. A soft cardiac murmur was frequently heard at the beginning, and was the result of the fever and anæmia, and was not due to endocarditis. If, however, this murmur persisted after defervescence, the patient was kept in bed and absolutely quiet for several weeks. Endocarditis occurred so frequently in acute rheumatism that it should be considered as a feature rather than a complication. In considering the differential diagnosis one should bear in mind that gonorrheal arthritis was usually monoarticular and did not respond to the salicylates. He had known joints previously affected with genuine rheumatism to become affected some years later in connection with an attack of gonorrhea. Such cases he looked upon as examples of subacute rheumatic arthritis plus gonorrhea. They would react more or less to the salicylates and to salol. The ordinary septic arthritis was usually a streptococci infection, and the effusion purulent. Acute osteomyelitis and necrosis of bone might be multiple and be mistaken for rheumatism. Gout and acute rheumatism would not be readily confounded if the attack were typical, but in other instances a search for deposits of urates about the joints would aid in the diagnosis.

The Complications and Sequelæ.—Dr. FRANK W. JACKSON discussed this topic from the viewpoint of his personal experience. He said that the complications of rheumatism were certainly very numerous, the principal ones being hyperpyrexia, delirium, coma and convulsions, tonsillitis, bronchitis, pneumonia, meningitis, pleurisy and inflammations of the other serous membranes and inflammations of the kidneys. True hyperpyrexia, meaning thereby a temperature over 105° or 106° F., and usually terminating fatally, was not frequent in this locality. Pure delirium due to rheumatism he had not seen. He had noted delirium in young subjects, but it had subsided promptly on stopping the salicylic acid. Coma and convulsions he had not seen. Acute rheumatic iritis, occurring in connection with acute articular rheumatism, was of occasional occurrence. There was certainly a distinct connection between certain forms of rheumatism and inflammations of the throat, but he was not sure that it was a distinct part of rheumatism. He did not feel sure that he had ever seen bronchitis as a distinct part of acute articular rheumatism, and this was in sharp contrast with the connection between gout and bronchitis. His experience had been the same with regard to pneumonia and rheumatism. Rheumatic inflammation of the meninges, he thought, must be exceedingly uncommon, for he could not recall having seen one such case. Inflammation of the pleura, however, was quite a different matter, for, rheumatic pleurisy was fairly common in this locality. He had seen a good many cases in which there seemed to be very little doubt as to the connection between the rheumatism and the pleurisy. They were, for the most part, cases of acute dry pleurisy, or a mild form of pleurisy going quickly to the formation of adhesions. Pleurisy with serous effusion was not common in connection with rheumatism. This relation between rheumatism and pleurisy was of practical importance, because it was easy to account for sharp pain in the chest in a rheumatic patient on the theory of its being muscular rheumatism, and hence one was apt to omit a physical examination, and so overlook the presence of a pleurisy. Peritonitis in connection with rheumatism undoubtedly occurred, but he had never seen such a case. Rheumatic inflammations of the kidneys were also of very great rarity, but he had seen it.

Pericarditis.—He had not happened to see a very large number of cases of pericarditis, and, according to his experience, it was not a very frequent complication of rheumatism. He was of the opinion that a good many cases of pericardial friction were not cases of pericarditis at all, but cases in which there was a plastic inflammation between the pleura and the external layer of the pericardium. In pericarditis there would be fever, pain over the pericardium, dyspnœa and rapid heart action, but these symptoms were often absent in this form of pleuropericarditis. For this reason he would distinguish between a pericarditis revealed by the rational symptoms and one made evident only by the physical signs. Pericarditis with effusion was less common than dry pericarditis. The recognition of a myocarditis as a part of an acute articular rheumatism was a matter of the greatest difficulty. Of course, when there was a pericarditis and an endocarditis present it was reasonable to assume that the myocardium was also involved.

Endocarditis.—A good many cases of endocarditis probably go unrecognized. Any valve of the heart might become inflamed and swelled without the production of a characteristic murmur. If a patient with acute articular rheumatism suddenly becomes worse without any change in the joint symptoms, one would naturally look to the heart, and if with this change there was an alteration in the heart's action, one would be justified in assuming the presence of an endocarditis, even though no murmur could be detected. It was quite common in cases of acute articular rheumatism for a murmur to be audible at the apex or base of the heart on one day, disappear the next, and perhaps alternate in this way for several days. Usually in the course of about a week, these cases develop a sufficiently characteristic murmur to justify the diagnosis of endocarditis. He was of the opinion that some patients absolutely recover from such an endocarditis, and he based this belief on careful study of some cases which he had followed for many years, and which presented subsequently a perfectly normal heart action. Again, many such persons were left with a crippled valve, but the compensation was so perfect that no harm resulted.

The Prognosis and Treatment.—Dr. William H. Thomson took up this part of the subject. He said that in a general way it might be said that acute articular rheumatism, which was now considered to be a microbic infection, ran its course in about six weeks. Aside from controlling the excessive pain, it was doubtful if the salicylates accomplished much—in other words, it was probable that they exerted their influence more upon the toxins than upon the organisms generating the toxins. Concerning the point of entrance of the infection into the system, the speaker said that it was highly probable that the tonsil was the point of entrance. Antecedent tonsillitis had been found in from [illegible] to 25 per cent. of cases of rheumatism. For this reason he favored as a prophylactic measure the douching of the throat with water impregnated with oil of peppermint. The profuse sweats of acute rheumatism he would ascribe as much to the peculiar derangement of the cutaneous circulation as to the infection. It was evident that the skin of a rheumatic person should receive careful attention from the physician. The patient should be dressed in flannel and lie between blankets, and the precordial region should be most carefully protected in this way. This was a most important prophylactic measure against relapse. He was strongly of the opinion that the modern displacement of the treatment of rheumatism by alkalies had led to a greater proportion of cases exhibiting heart complications. Aconite was most useful in securing the needed rest to the heart. The anæmia of rheumatism was quite *sui generis*, and iron in such cases was mischievous. Cod liver oil was especially indicated. The salicylates were most useful, but, like all really good remedies, they required to be used with discrimination. The sodium salt now and then excited delirium or was depressing. Many young subjects do better with the salicin itself in doses of fifteen or twenty grains. It was often well to omit the salicylates altogether, and prescribe lemon juice instead. He preferred the strontium salts to the salicylates.

Dr. Morris Manges said that all our knowledge of rheumatism pointed to a microbic infection, but as yet the evidence in this direction was most contradictory, and showed the necessity for further research. Possibly the solution of the whole question lay in assuming various germs as being among the etiological factors. Leube said that muscular rheumatism was really a masked form of acute articular rheumatism, and that both were different phases of a bacterial process. The chemical theories had been of service as pointing out the value of the alkaline treatment. He was disposed to think that even more than 25 per cent. of cases of acute articular rheumatism showed antecedent tonsillitis. The anæmia of rheumatism was a very impressive feature of that disease. He could not agree with Dr. Thomson that iron was injurious in this form of secondary anæmia. He made use of the milder ferruginous preparations, the organic rather than the metallic ones. He would endorse the view already expressed this evening that endocarditis should be looked upon as a part rather than as a complication of rheumatism. Dr. Jackson had spoken none too emphatically of the false or pleuropericardial murmurs. Such murmurs occur sometimes in connection with acute osteomyelitis. Cases of adherent pericardium were frequently found at autopsy, though overlooked during life. Such a condition ordinarily originated in connection with tuberculosis, nephritis, or rheumatism, particularly the latter. Many of the heart murmurs heard during an attack of rheumatism were hæmic or myocardial, thus from day to day explaining the small variations alluded to by Dr. Jackson. The best medical treatment for rheumatism was a combination of the alkaline treatment with the salicylates. It was remarkable how difficult it was in many such cases to keep the urine alkaline. The rule should be to give the alkali in sufficient quantity to keep the urine alkaline. In some especially difficult cases it would be necessary to give [illegible] potassium in doses of ten drops every three or four hours. Rest in bed during convalescence from acute articular rheumatism was of the utmost importance.

Therapeutic Hints.—Dr. [illegible] was of the opinion that the principal reason for disappointing results with the salicylates was to be found in the use of inadequate doses. For the last six or eight years he had made use of the pure salicylic acid made from the oil of wintergreen in combination with bicarbonate of soda, thus making the salicylate of soda extemporaneously. He generally gave it in doses of twenty grains of pure salicylic acid combined with [illegible] grains of sodium bicarbonate. If possible he avoided giving it until 4 o'clock in the afternoon, and repeated it at intervals of two hours until eighty grains had been taken. There was no use in giving the salicylates unless tinnitus aurium was produced, but most of this would pass off during the night. The treatment of the disease was assisted by the application of a cold wet compress to the affected joints. The compress should be made of three or four thicknesses of linen wrung out of water at 60° F., and covered with a layer of flannel. The compress should be renewed at intervals of two or three hours. If the fever were quite high the compress should be applied very wet. As a rule, he did not employ these compresses unless the body temperature was over 102° F. As a rule, an ice bag should not be applied continuously for more than half an hour, for it produced a localized [illegible] by a paralysis of the cutaneous circulation. The ice bag should be applied in this intermittent manner over the precordium.

The Microbic Theory of Rheumatism.—Dr. Abraham Mayer said that notwithstanding all that had been said by Dr. Stern regarding the bacteriology of this disease, we were still very far from knowing the exact cause of rheumatism. There were very few physicians at the present day who did not believe in the bacterial nature of rheumatism, but the exact germ responsible for it was still unknown. Long ago English and American physicians had called attention to the angina which preceded attacks of acute articular rheumatism, and supposed the infection might arise from this point. He agreed with Dr. Manges that more than 25 per cent. of cases of acute articular rheumatism are preceded by tonsillitis. A diplococcus had been found on the tonsils, which would grow on certain culture media and change into a streptococcus. Singer had found in five cases of acute articular rheumatism a larger streptococcus invading the tissues in various parts of the body. Injections of Meyer's delicate streptococcus into animals invariably gave rise to the peculiar temperature curve of acute articular rheumatism, and often produced effusions into the joints and pleuræ. However, the same results had been produced by the injection of other microörganisms. Such experiments forced us to believe that acute articular rheumatism was not an entity, but was caused by various germs. If this were so, then it was easy to understand why the salicylates would not prove to be specific in all cases.

Impure Salicylate Dangerous.—There are three kinds of salicylate: (1) That made by synthesis; (2) That made from the synthetic oil of wintergreen, and (3) That made from pure oil of wintergreen. The impure varieties commonly cause delirium; the pure sodium salicylate rarely does this. He often gave as much as 120 grains of the pure sodium salt in the twenty-four hours, and rarely produced delirium. With regard to the use of iron in persons suffering from rheumatism, his experience fully coincided with that of Dr. Manges.

Dr. **Andrew H. Smith** commented upon the change in the type of rheumatism in recent years. He said that in the earlier years of his practice he saw cases in which the patient suffered excruciating pain, but he rarely sees such cases now, and he was inclined to attribute this to the introduction of the salicylate treatment. In his hospital practice he was accustomed to keep the urine of rheumatic patients alkaline by the administration of a mixture composed of equal parts of the acetate, bicarbonate and the citrate of potassium. He thought there could be no doubt about the close relation between tonsillar inflammation and acute articular rheumatism. He thought he had aborted a number of cases of peritonsillar inflammation by the use of the same treatment that he would employ in acute articular rheumatism. Mention was made of one case in which a pericardial murmur developed twenty-four hours before the first signs of an acute articular rheumatism. As a local application in acute articular rheumatism he often made use of equal parts of guaiacol and glycerin, and the patients found this very comfortable. He had but little difficulty in getting patients suffering from acute articular rheumatism about three-fourths well, but the chief difficulty experienced was in bringing them through the last quarter. For some time after the temperature had reached the normal the patient should be confined to bed.

Dr. **Louis Fischer** said that in cases of acute rheumatism occurring in children he had observed vomiting, fever, anorexia and malaise. His hospital records showed that in the cases of polyarthritis 70 per cent. developed heart complications and 11 per cent. of the cases terminated fatally. If necessary, the affected parts should be kept at rest by bandages or plaster of Parish. The dietetic treatment was more important than the medicinal. A sulphur bath at 75° or 85° F., lasting for an hour, had been found to give relief to the pain. About two ounces of the sulphuret of potassium should be added to the water in a bath sufficiently large to bathe the whole body of the child. A 10 per cent. ointment of the salicylate of methyl, applied over the affected joint, would relieve the pain in some cases. Incidentally, the speaker expressed the belief that in many cases of diphtheria treated with antitoxin the polyarthritis had nothing whatever to do with the use of antitoxin, and was the result of the infection with the Klebs-Loeffler bacillus.

Dr. **James J. Walsh** remarked that, after all, the valves of the heart were only joints, and hence, rheumatic endocarditis should not be looked upon as a complication but as a part of the rheumatism.

Dr. **Kinch** of Westfield spoke of an interesting case of rheumatism, in which the manifestations of that disease had remained in abeyance during an intercurrent attack of diphtheria, but had reappeared on the subsidence of the diphtheria.

Dr. **Heinrich Stern** said that the great number of bacteria found in connection with rheumatism seemed to him to throw considerable doubt upon the microbic theory. To his mind, there was a general constitutional condition predisposing to bacterial invasion, and the nature of the infection determined the special features of the individual case. The salicylates act as would the tartrates or any other organic acid, not chemically, but mechanically; the salicylates act in rheumatism by increasing the osmotic tension of the blood.

Dr. **William H. Thomson** expressed his belief that we were very near the identification of the bacterial cause of rheumatism. He had never been satisfied with the investigations of Meyer and of Singer, but it was very different with the investigation of Wassermann and others following him. They had found a bacterium, cultivated it outside of the body, injected it into a number of animals, found it again in the joint effusions and in the pericardium, had recultivated it and, in one case, reproduced the disease by five different generations of the same bacterium. This same bacterium, found in the effusions of the knee and pericardium in man, when injected into animals gave rise to the same conditions. He thought Wassermann's bacterium would be found to be the ultimate cause, and he distinctly disagreed with the notion that such a definite disease as rheumatism can be due to a number of bacteria.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 24, 1902.

Frank Van Fleet, M.D., President.

Pathology and Bacteriology of Empyema.—Dr. **David Bovaird** read this paper, which was based on observations, in the New York Foundling Hospital, on 101 fatal cases of empyema, occurring in children ranging in age from seventeen days to eight years. He said that empyema was relatively, as well as absolutely, more frequent in children than in adult life; and was also more fatal. The affection was, in the majority of cases, unilateral, though it might occur bilaterally. Thus, of the 101 cases under consideration, seventy-seven were unilateral and seventy-four bilateral. The part of the pleura most often affected was that covering the lower lobe. In six cases out of the series tuberculosis of the bronchial lymph nodes was present. The thick purulent exudate was regularly of a distinctly greenish color. The unusual consistency of the exudate in children was of importance, particularly in connection with exploratory puncture as a means of diagnosis. There was no sharp distinction between serofibrinous pleurisy and empyema in children. Sacculation was much more frequent in children than in adults. The quantity of the effusion was usually remarkably small, even in the fatal cases. It was rarely more than seven or eight ounces, and often not more than one or two ounces. The empyemas of children, in his experience, had not perforated the chest wall or other parts. The lungs were compressed, without other lesion, in thirty-five out of the 101 cases and consolidated in part in sixty-six cases. The consolidation was lobar in ten, bronchial in twenty-seven and of an indefinite type in fourteen cases. It was associated with tuberculous lesions in four, with small abscesses in six and with gangrene in five cases. The associated lesions of empyema were practically inflammation of other serous membranes, such as the pericardium, meninges and the peritoneum. The pneumococcus was responsible for the empyemas in children in the great majority of cases, and in such the exudate is thick and creamy. When the exudate was thinner the streptococcus or the staphylococcus was generally present. It was safe to say that primary tuberculosis of the pleura, in children at least, was extremely rare. Of the 101 cases tuberculous lesions of the body were found in only six cases, and in only one tuberculosis of the pleura itself.

Clinical Features of Empyema in Children.—Dr. **Henry Koplik** considered in this paper the etiology, symptomatology and prognosis, basing his remarks largely on his experience in the Mount Sinai Hospital. His cases numbered 120. Sixteen of these were less than one year old. There seemed to be a special tendency to suppuration in pleurisy, as in other inflammations occurring in children. In sixty-nine of his cases pneumonia was probably the primary cause, as the pneumococcus was present. The tubercle bacillus was found in only seven cases. In infants and children empyema is an acute infection following the acute infectious diseases, tonsillitis, mediastinal abscess and chronic gastro-intestinal catarrh. In the majority of cases the effusion into the pleura has the gross characteristics of ordinary pus. In some instances the effusion consists of cloudy serum, [illegible] in his patients. Hæmorrhage appeared in children but not the serious consequences that it possessed in the adult. He had seen a number of hæmorrhagic exudates which did not appear to be tuberculous, or to be the products of the pleura. Of his 120 cases three were hæmorrhagic. All three gave the streptococcus but not the tubercle bacillus on the cover-slip, and all three patients recovered. The disease was masked by the symptoms of the primary disease. The persistence of an elevated temperature and a rapid pulse after pneumonia was suspicious of empyema. In some cases the pneumonia and the empyema are concomitant and give rise to marked symptoms; in other cases the onset of the empyema was more insidious. Exhausting night sweats, and a distinctly intermittent temperature, with increased frequency of respiration, point strongly toward empyema, but there are no pathognomonic signs of empyema. The signs of fluid in the chest of a child were different from those found in the adult, and if the chest were full of fluid the difficulty of diagnosis was increased. The pleural cavity might be filled with fluid and still the voice and respiratory murmur be only slightly diminished both anteriorly and posteriorly. Bronchophony and bronchial breathing might be heard in some cases all over the chest. The percussion note posteriorly was flat, and there was a peculiar and characteristic sense of resistance imparted to the finger. On the left side displacement of the apex of the heart and on the right side, of the liver downward were useful as confirmatory signs. Encapsulation of fluid was most apt to occur between the lobes of the lung. In certain localities the diagnosis of fluid must be made with reserve, and in all cases the diagnosis should be made positive by exploratory puncture. This should never be omitted, and should be done with the patient in the upright posture. If no fluid were obtained at the first attempt, and the symptoms continued without abatement, another exploratory puncture should be made after a reasonable time. Of 120 cases operated upon in his hospital service twenty died. Of the fatal cases four died within one to five days after admission, and in these not the operation, but the delay in coming under observation was the real cause of death. Pneumonia, either persistent or recurrent, caused the fatal issue in eleven cases. The complication most to be feared was bronchopneumonia after operation. It might involve the lung of the operated side. He had not been able to find the cause, though it seemed to be a reinfection traceable to the presence of infectious matter in the system at the time of the operation, though then dormant.

Surgical Treatment of Empyema.—Dr. CHARLES N. DOWD presented this paper, which was based on his experience in St. Mary's Free Hospital for Children. There were seventy-five cases, seventy-three of which were under the age of fifteen years. The cases were conveniently divided into three groups, viz.: (1) Simple empyemas which recovered within three months; (2) Protracted empyemas; and (3) The fatal cases. Most of the first group were due to the pneumococcus and many of the protracted cases were tuberculous. In the simple cases there was considerable effusion, with compression of the lung, but very little thickening of the pleura. In the second group there was not much effusion but considerable thickening of the pleura. A very similar condition prevailed in the third group. The ordinary treatment had been to excise, under anæsthesia, about an inch and a half of the eighth rib in the posterior axillary line. The pus and coagula were allowed to escape and then a large absorbent dressing was applied. The patients were encouraged to get up as early as possible, and expansion of the lung was favored by having the children blow through a tube, forcing water from one bottle to another. In the protracted cases portions of the chest wall were removed according to the methods of Estlander and Schede. There were forty simple empyemas. None of these healed in the first month, [illegible] in the second month, and the remainder in the third month. This was the class of cases most often seen in private practice, and about which the question was often raised as to whether aspiration or incision should be employed. He saw no objection to making use of the simpler methods in this group of cases, provided more radical methods were promptly resorted to if the progress of the case were not satisfactory. There were twenty-four cases of protracted empyema. In four the pus perforated the chest wall; in two it perforated the lung; in one there was abscess of the lung; in one pus perforated the diaphragm; in three there was empyema on both sides; in three there was tuberculosis with healing; in four no definite reason could be assigned except the extent and severity of the disease. Five of the fatal cases should also be counted among the protracted cases. Of the protracted cases, 35⅓ per cent. had tuberculosis or some other complication which was responsible for the protracted course of the disease. The earlier cases of this series were treated by Estlander's operation, and the others for the most part by the Schede operation, but in a few instances a portion of the thickened pleura was stripped from the lung in order to allow better lung expansion. This last method seemed to him a distinct improvement in the treatment of empyema. The deformity would be less and convalescence would be hastened by this operation. In this connection Dr. Dowd exhibited three patients. One of them was a boy in whom the empyema had perforated the chest wall in two places. Resection of rib was done at first, and later a portion of the chest wall was removed and a portion of the pleura was stripped off. There was now only very moderate deformity, and the boy had been in excellent health for two years since the operation. The second case was that of a boy who had first been operated upon for empyema in 1897. He was proved to be tuberculous, yet the very severe empyema had practically healed, and his general condition was quite satisfactory. Dr. Fowler had recently reported thirty cases of decortication of the lung for empyema. Of this number seventeen had been cured, nine were unimproved, three had died, and in one the result was doubtful. A study of the fatal cases impressed one with the importance of tuberculosis in empyema, and led one to look upon empyema as not a disease in itself but a complication of other diseases.

Fluoroscope Useful in Diagnosis of Empyema.—Dr. J. E. STUBBERT said that he had found a very useful means of diagnosis in cases of empyema to be examination of the chest with the fluoroscope and the x-ray. This gave even more positive results than puncture, the picture being especially characteristic of empyema when pulsation of the fluid was visible on shaking the patient. He had heard nothing said about the treatment of the protracted cases by the injection of antiseptic fluids into the pleural cavity. A case was narrated in which the treatment had consisted in the injection of a solution of ichthyol in glycerin. At first a 10 per cent. solution was injected through the drainage tube twice daily, and the strength of the solution was gradually increased until finally 120 minims of a 90 per cent. solution were injected three times a day. When the strength of the solution reached 50 per cent. the temperature of the patient began to fall and the character of the discharge improved. In the operative cases of empyema the expansion of the lung could often be very materially improved by the use of a rubber valve over the opening in the chest.

Methods of Favoring Lung Expansion.—Dr. ANDREW H. SMITH thought it was of the utmost importance that an empyema should not be allowed to go on to the extent of causing compression of the lung. The lung, when compressed, became encysted, as it were, in an unyielding bag, very much like a ham sewed up in a canvas bag. The operation originally suggested by Dr. Fowler of Brooklyn, of stripping up a portion of this very tough envelope, had entirely changed the treatment of the severe cases of empyema. Formerly, if the lung could not be made to expand satisfactorily, various mutilating operations were done in order to make the chest wall meet the lung. In the milder cases expansion could be increased by the forcing of air from the sound lung into the diseased one. This forcing of air occurred whenever there was cough, but if the patient were instructed to take a deep inspiration and try to make expiration while holding the nostrils, this dilating effect would be greatly enhanced. The value of the method was that it required no apparatus and could be practiced many times a day by the patient. Expansion of the lung was also favored by a process of traction from without, arising from the traction force of the chest wall upon that portion of the lung which was adherent to the lung by granulation tissue. The former practice of *freely* irrigating the pleural cavity was to be condemned because it served to break up the adhesions. The use of small quantities of antiseptic fluids, as suggested by Dr. Stubbert, was a different matter. Sometimes when the drainage tube was not shortened soon enough, the purulent discharge would persist, and it would be found, by injecting a measured quantity of water, that the tube was in reality in a sinus. Whenever such a condition was detected it should lead to the immediate shortening of the tube. When the pleural cavity was completely filled the auscultatory sounds must be transmitted through the fluid to the chest wall, whereas if the pleural cavity were only partially filled these sounds would be partly above the level of the fluid.

Dr. CHARLES G. KERLEY said that he had never met with cases in which bronchial breathing was very plainly heard over the chest, both front and back, that pleural effusion was not present. Mention was made of a case in which a dangerously profuse hemorrhage had occurred on incising the thickened pleura, and subsequently, at autopsy, it was found that the vessels of the pleura were enormously enlarged. So profuse was the hemorrhage that it was necessary to pack the wound with gauze and make pressure in order to avert death on the table from loss of blood.

Dr. ROWLAND G. FREEMAN said that his experience with empyema in children impelled him to emphasize the need of great watchfulness in cases of pneumonia that do not resolve promptly. If the sounds on auscultation become distant it was well to make an exploratory puncture at once, and if such a puncture were made it should be done with a large needle. The experience at the New York Foundling Hospital showed that simple incision and drainage were sufficient, and that it made no difference at what point in the pleural cavity the opening was made.

Technique of Drainage for Empyema.—Dr. CHARLES L. GIBSON said that he was inclined to look upon a tuberculous empyema as a cold abscess, and to treat it as a cold abscess in any other part of the body would be treated. Some cases of tuberculous pleurisy, in adults at least, do badly after the evacuation of the fluid. It was thought that the relief of the venous congestion resulting from the removal of pressure explained this bad effect. For these reasons he was disposed to leave tuberculous pleurisies alone. Even in small children resection of a rib could be done very satisfactorily under anæsthesia produced by nitrous oxide gas. As soon as the incision had been made the opening should be closed with the finger until an accurately fitting tube can be inserted. Gauze is packed around the tube and between it and the chest wall, and the tube is covered with a rubber valve. While this is being done none of the fluid is permitted to escape, and hence the child is not disturbed by a sudden change in the equilibrium of the thoracic pressure. After the insertion and arrangement of the tube the usual voluminous dressing is applied, and the chest is thus gradually drained into the dressing.

Natural History of Empyema.—Dr. FLOYD M. CRANDALL said that empyema should be looked upon as a disease of childhood which sometimes occurs in adult life. At one time he had met with three cases in close succession, which illustrated well the natural history of empyema in children. In the first case the empyema had existed for sixteen weeks, but the patient recovered. The second case had begun with pneumonia. Perforation of the empyema occurred about five months later, but two and a half months more elapsed before consent could be obtained to operate. The child recovered. The third case also started with pneumonia, and perforation occurred after five months. Operation was refused, and the child died twenty-two months later of tuberculosis. Dr. Crandall said that it was dangerous to allow these cases of empyema to run on to spontaneous opening, for practically recovery never takes place under such circumstances; moreover death occurs many times before such an opening takes place. He had found that, in very young children, simple puncture would usually be followed by prompt recovery, though a more radical operation was frequently wise and often necessary. The greater the delay the more radical must be the operation.

A Modified Operation.—Dr. ARTHUR I. BOYER described a method of operating that he had employed with success in an adult coming under observation quite late. Under chloroform anæsthesia a glass nozzle, connected with a fountain syringe, placed at a height of six feet, was introduced, and normal saline solution, at a temperature of 100°F., allowed to gradually displace the 1,500 cc. of pleural effusion. By this method the danger of hemorrhage was obviated. For the first two days after the operation an absorbent wick was used to drain off the saline solution. The patient made a good recovery in three weeks.

An Improved Technique.—Dr. SAMUEL LLOYD said that 58 per cent. of the cases of empyema in the babies' wards of the New York Post-Graduate Medical School and Hospital had shown the pneumococcus. He thought nearly all surgeons would agree with the treatment laid down by Dr. Dowd, but he would differ a little as to the technique. The anæsthetic should be stopped on exposing the pleura, and the finger used to break up the adhesions. The lung then expands, and the child, coming out of the anæsthetic, cries or coughs, and so assists in this expansion of the affected lung. It was remarkable how promptly and well the lung would expand under this simple breaking up of the more recent adhesions. In the cases of long standing the adhesions were so firm that nothing short of an Estlander operation, or similar radical measure, would suffice. Dr. Furness had had rubber drainage tubes made with a soft rubber flange on the outer end to prevent the tube from falling into the pleural cavity. He had used these tubes with much satisfaction.

A New Empyema Drainage Tube.—Dr. F. N. WILSON said that he had devised a self-retaining tube, and one which would not cause any irritation of the lung when the latter had expanded. The tube is very short, and has a soft rubber flange on each end. By folding up the flange on the pleural end, the tube can be easily introduced, and can be as easily removed. These tubes are made in two sizes, one for children and one for adults. Dr. Wilson exhibited the tube.

Dr. BOVAIRD said he desired to emphasize the fact that empyema may occur entirely independent of pneumonia, and that it was very apt to go unrecognized even by expert clinicians.

Dr. KOPLIK said that he was surprised at the large proportion of bilateral empyemas occurring in Dr. Bovaird's cases. This might perhaps be explained by the fact that many of the children were under two years of age. Out of his own 120 cases only two were bilateral, as determined by clinical observation. Of course these statistics

[illegible]

[illegible]

Demonstration of a Method of Seeing the Curvatures of the Stomach with the Naked Eye.—Dr. Max [illegible] gave this demonstration. The clothing having been removed from the abdomen, the patient is instructed to take deep inspirations, and while this is being done, the observer stands at the [illegible], and brings his eye to the level of the abdomen. The movements of the organ under the abdominal wall may be seen quite easily in this way, even when the abdominal walls are quite thick. [illegible]

Dr. H. S[illegible] said that this method of examination often failed, and was hardly available in cases of gastric dilatation or gastroptosis. The outline of the organ could be seen just as well from the foot as from the head of the patient. This mode of examination had been described twenty years or more ago, and he had employed it frequently.

Disposition of Stable Manure.—On recommendation of the Committee on Hygiene, the society adopted a resolution requesting the health department to require the compression or baling of manure and its removal from stables in suitably covered receptacles.

Therapeutic Hints.

Typhoid Treated by Chlorine.—Put thirty grains of chlorate of potassium in a dry bottle and add sixty minims of hydrochloric acid. Allow to stand until the chemical action is complete, then add twelve ounces of distilled water, little by little. Give a tablespoonful every two hours until the stools become less offensive, then at longer intervals. —Peck.

Tonsilitis.

℞	Quininæ hydrobromat.	gr. i
	Sodii benzoat.	gr. i
	Salol	gr. v

M. ft. cap. S. One every three hours.

—Abraham.

Incoercible Vomiting of Pregnancy.—Rectal injections of artificial serum (deci-normal saline solution), of a daily dosage of three or four quarts, divided into enemeta of ten ounces each. The liquid should be warm, and injection practised very slowly (ten to fifteen minutes). In case of intolerance, a few drops of laudanum might be added, or resort to hypodermoclysis. Treatment should last ten days, during which time the patient should receive no nourishment, either solid or liquid. After this interval commence giving liquids, and gradually return to solid food.

—Constamin.

Reflex Vomiting in Children.

℞	Ol. absinthii	gtt. $\frac{1}{6}$
	Sodii bicarb.	gr. ii.
	Aq. menth. pip.	℥i

M. S. Every half hour until relieved.

Lobar Pneumonia.

℞	Tinct. aconiti	♏[illegible]
	Tinct. digitalis	♏[illegible]
	Spir. frumenti	℥[illegible]

M. S. Dose every three hours.

Gall-stone Colic.

℞	Potass. iodid.	2.5
	Aq. destil.	150

M. S. ʒss.–ʒi t. i. d.

—F. Gar[illegible]ki.

Scarlatinal Angina.—

℞	Sozoiodol. sodium	
	Sulphuris precip.	āā ʒss

M. S. Insufflate several times a day.

Rheumatic Arthritis.

℞	Salicylate of methyl	ʒv
	Chloroform	ʒ[illegible]
	Menthol	ʒss
	Lanolin	ʒ[illegible]

M. ft. mist. S. Apply [illegible]

Hemorrhoids.—

℞	Vaselin	℥i
	Cocain. hydrochl.	gr. [illegible]
	Morphin. mur.	gr. vi
	Hydrarg. [illegible]	gr. xl

M. S. Apply night and morning. If itching, apply [illegible]

Anthrax.—[illegible] injections of [illegible] of a 1 per cent solution of collargol (Credé).

Tetanus.—Injections of a 1 per cent solution of [illegible]—A. [illegible]

Atonic Dyspepsia.—Chief indication is to prevent distention, to avoid over-distention, either by giving small meals at shorter intervals than usual, or by allowing fairly substantial meals at longer intervals than usual. The latter is the better if appetite is good.

As regards character of food: (1) reduce quantity of fluid taken with food to a minimum, and (2) select compact, nutritious food, such as meat, lightly boiled eggs, and easily digested cereals, as flaked wheat or oatmeal. Milk taken alone is eminently unsuitable. Animal food is preferable to vegetable, and such vegetables as are prescribed should be pulped. Easily fermentable food, sugar and preserves should be avoided. Soups sparingly. Light wine may be permitted to stimulate appetite.

Rest for at least twenty minutes after each meal, abdominal exercise, massage, loose clothing. The Scotch abdominal douche is valuable in some cases.

Medicinal: Strychnine with arsenic and sodium bicarbonate given before meals, or combined with muriatic acid and pepsin, given after meals. —A. H. Carter.

Dermatitis Serpiginosa.—Brush surface with a strong solution of nitrate of silver, or apply moist compresses of rectified alcohol. The latter is also useful in the intertrigo of fat people.

Flatulent Dyspepsia.

℞	Magnesia	
	Phosphate of lime	
	Powdered charcoal	
	Sublimed sulphur	āā 10.0

M. S. Teaspoonful in water p. r. n.

Enema in Tympanites.

℞	Tinct. asafetidæ	ʒii
	Spir. Terebinth.	ʒi
	Magnes. sulphat.	ʒ[illegible]
	Aq. ferv.	O[illegible]

M.

Pleurisy.—

℞	Morph. acetat.	gr. ½
	Potass. acetat.	ʒss
	Tinct. veratr. virid.	♏xxiv
	Syr. tolu	ʒss
	Sol. potass. citrat.	ʒiiss

M. S. Dessertspoonful every three hours to lessen probability of effusion. —Da Costa.

Report of Cancer Laboratory, University of Buffalo.—Roswell Park says that the results of the past year's work have been to strengthen the ever-growing conviction that cancer is an infectious disease; also that cancer is on the increase. The problems involved in connection with parasites which may play a rôle in the production of cancer, and their culture on artificial media, have been studied; efforts have been made to acclimatize yeasts, fungi, protozoa and the like to development in living animals, and then conditions were chosen which, from a theoretical standpoint, would be most likely to lead to the formation of tumors by this means. On the other hand, every effort is being made to cultivate parasites from cancerous material on artificial media, and to facilitate their growth and development in animals. Investigations of a toxicological and physiological nature have been carried out, the problems of the disease from a chemical standpoint, and a considerable number of experiments, especially of a microchemical nature, have been carried on with a view to confirming and supporting the work of the pathological department. No small part of the work has consisted in examining, indexing, and comparing the work and results of others in all parts of the world. X-ray apparatus has been promised for the experimentation of the treatment of cancer by this means.—*Buffalo Medical Journal*, March, 1902.

New Instruments.

NEEDLE-HOLDER.

By HENRY H. MORTON, M.D.,

CLINICAL PROFESSOR OF GENITO-URINARY DISEASES IN THE LONG ISLAND COLLEGE HOSPITAL, AND GENITO-URINARY SURGEON TO THE LONG ISLAND COLLEGE AND KINGS COUNTY HOSPITALS AND THE POLHEMUS MEMORIAL CLINIC.

THE writer has endeavored in vain for some years to find a needle-holder that was entirely satisfactory.

Some forms which seem quite popular are provided with a catch to prevent separation of the handles after the jaws are closed upon the needle. This catch is often the cause of the needle's breaking, is troublesome to work and is, in the writer's opinion, entirely unnecessary.

The ordinary needle-holder will not hold a Hagedorn needle unless especially designed for the purpose, while, for general use, the writer prefers a three-cornered needle with a moderate curve; for certain purposes, such as introducing retraction sutures through the bladder in suprapubic cystotomy, or sewing up the inguinal canal in Bassini's operation, the extreme curve, which is only found in the Hagedorn needle, is very convenient.

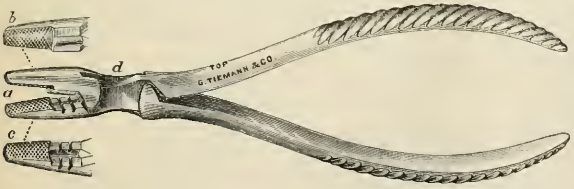
The Deeffenbach needle-holder, which is a simple instrument and without a catch, has been found fairly satisfactory, and has been used for some years. Its disadvantages are the long handles, which are rather heavy and clumsy, and as the jaws are made perfectly flat they are of necessity quite narrow, to avoid breaking the needle: in consequence they do not hold the needle as firmly as they ought, and the size and weight of the instrument prevents a very fine needle being held in it to good advantage.

It is a common experience with all surgeons that complicated instruments may work well in the shops of the instrument-makers, but their shortcomings become only too evident when brought into actual use in an operation.

For this reason all instruments which approach the simple type of the tools used by mechanics in their daily work at the bench, are the most efficient instruments which the surgeon can make use of.

With this thought in mind the writer selected, from the stock of a large hardware store, two varieties of pliers or pincers, one with flat, broad, powerful jaws, used for holding wire, and the other used by umbrella-makers, with a concave lower jaw, into which the convex upper jaw fits closely when closed.

With these tools as models and some suggestions from the writer, Messrs. Tiemann & Co. constructed the accompanying form of needle-holder:



a—Concave and convex jaws. *b* and *c*—Jaws in detail. *d*—Open box joint.

Description.—The posterior part of the lower jaw is grooved in the center, leaving two ridges, which are notched to receive Hagedorn's needles. An elevation on the opposite jaw fits into the groove and firmly holds in place any size of Hagedorn's needles.

The forward part of the lower jaw is concave, while the upper jaw is convex, and both are serrated with fine cross cuts.

These jaws will grasp and firmly hold any size of the ordinary curved surgical needles, without breaking it. The writer has used this needle-holder in several operations, and has found it to be eminently satisfactory.

The advantages it possesses are as follows: (1) It can be taken apart and boiled; (2) There is no catch to break needles or embarass the surgeon; (3) The needle is held firmly; (4) It will hold the largest or smallest size of curved surgical needle; (5) It holds a Hagedorn needle equally well.

40 SCHERMERHORN STREET, BROOKLYN.

Surgical Suggestions.

Benzine is one of the best things for cleansing the skin after ointments have been used, and for removing sticking plasters. It is cheaper than ether, does not produce a cooling effect, and causes no irritation.—FRANKS.

Chancroid.—

℞	Creosote	♏iij.
	Hydrarg. bichl.	gr. iv.
	Glycerini	℥ij.
	Aquæ Rosæ	ʒiij.

M. S.: Apply frequently as a wash.

Pruritus Vulvæ.—

℞	Cocaine	2.0
	Orthoform	1.5
	Menthol	0.5
	Carbolic acid	1.0
	Vaseline	20.

M. S.: Apply.

Cauterize excoriations with a 10-per-cent. silver solution.

Umbilical Hernia.—A new method advocated calls for an overlapping of the fascia of the external oblique.—"Steps of Operation" in *Annals of Surgery*, August.—W. J. MAYO.

Recent Fractures.—A prolonged experience of the use of the combined methods of massage, early movements, and rational posture in the treatment of ordinary fractures confirms the writer in the favorable estimate formed by him as reported in his first communication upon the subject in *The Lancet* of 1897.—Sir W. H. BENNET, *The Practitioner*, August, 1901.

In Chronic Cystitis irrigate the bladder daily with a quarter to a half per cent. solution of formaline.

The Uvula, when elongated, may produce chest symptoms suggestive of phthisis, and may even predispose to the latter. An irritable cough associated with persistent infrascapular pain has been promptly cured by removing the uvula.—LENNOX BROWNE.

Disinfection of Instruments.—The official spirit of soap of the German Pharmacopœia offers a convenient means of effectually sterilizing surgical instruments. This spirit is made by combining six parts of olive oil with seven parts of caustic potash, subsequently diluting with thirty parts of alcohol and seventeen of water. The caustic action of the potash is neutralized by the olive oil and water.

Instruments thoroughly washed with this solution, or simply wrapped snugly in cotton saturated therewith, may be kept aseptic for considerable periods of time. Exclusion of air is an important consideration.

The same agent may be employed to disinfect the hands of the operator, or skin of the patient, as it is harmless even when applied in full strength.—*Deutsche Medizinal Zeitung*.

Urethral Chill.—To ward off urethral chills as the result of passing sounds, etc., the following is recommended:

℞	Sulphate of morphine	grs. 1-10.
	Tincture of aconite	♏ij.
	Oil of wintergreen	♏xv.

For one dose. —WEIR.

Medical Items.

Contagious Diseases Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 29, 1902:

	Cases	Deaths
Measles	681	[illegible]
Diphtheria and croup	339	46
Scarlet fever	328	22
Smallpox	69	4
Varicella	68	
Tuberculosis	295	166
Typhoid fever	18	[illegible]
Cerebrospinal meningitis	..	6

Divorce Statistics.—Connecticut, once regarded as the worst of Eastern States in respect to easy divorce, now shows some improvement as compared with the increase of population, and even absolutely; for she has granted fewer divorces in the last seven years than in the preceding seven. A better public sentiment and a more careful procedure of the courts seem to be the chief reasons for this. The ratio of divorces to marriages is now 1 to 15.8. In earlier years it was as high as 1 to 9. Rhode Island, on the contrary, now grants four hundred or more annually, or 1 in [illegible] marriages. In Massachusetts divorces are increasing, though as yet the ratio is not more than 1 in [illegible], and the number granted in 1900 was [illegible]. One divorce to fifty marriages is about the highest ratio known in New Jersey.

Three or four typical States in the interior give some startling figures. Divorce in Oklahoma increased from 2,270 in 1889 to 3,217 in [illegible], and the ratio to marriages has become 1 to 10.9. There were 2,418 divorces in Michigan in the year 1900, or 1 to 9.8 marriages. Here about two-thirds of the applications are granted. In some States three-fourths of the suits are successful. In Michigan the statistics show that nearly all the divorces are granted to residents of the State. Indiana shows a remarkable change for the worse. About a generation ago Indiana was notoriously bad. Then the laws were improved and her divorce rate was no worse than that of some States in the East; but for some unexplained reason divorces of late have increased rapidly.—*Michigan Monthly Bulletin of Vital Statistics.*

Mosquitos Attracted by Sounds.—Dr. S. M. Lawrence, Port of Spain, Trinidad, writes to the *British Medical Journal* concerning the fact observed by a correspondent to that paper that certain sounds attract mosquitos. Dr. Lawrence says that in his childhood days, with others, a favorite amusement at dusk was to attract and kill mosquitos by these means. His companions and he would vie with each other in hitting on the note that would prove most attractive to these pests, which so far as he can remember was a continuous [illegible] uttered in a [illegible] key, and then suddenly changed to a lower [illegible]. [illegible]—proceeds Dr. Lawrence—in the [illegible] of the sudden rise in the [illegible] and the equally sudden attack on the part of [illegible] the imitation. [illegible] not only for amusement, but also to put a stop to their unwelcome attentions.

The Doctor's Conscience.—The following tale, which [illegible] is told of a deceased well known London physician whose pride it was to declare that he could feel a patient's pulse, auscultate him, write a prescription, and pocket a fee in a space of time varying from three to five minutes.

One day a man was shown into the consulting room and was rapidly examined. At the conclusion he shook hands with the doctor and said:

"I am especially glad to meet you, as I have often heard my father, Colonel ——, speak of his old friend, Dr. ——."

"What," cried the doctor, "are you Dick ——'s boy? My dear fellow, fling that prescription into the fire and sit down and tell me what is the matter with you."

Bakers' Teeth.—A dentist has called attention—says a London weekly journal—to the deplorable condition of the teeth of bakers, and asserts that he is often able to tell the profession of his patients by the condition of their teeth. The tooth decay is soft and rapidly progressive. The principal parts attacked are the outside surfaces of the teeth, commencing at the top of the gum and rapidly extending to the grinding surface.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended March 29, 1902:

SMALLPOX—UNITED STATES.		Cases	Deaths
California, Los Angeles	Mar. [illegible]	1	
Sacramento	Mar. [illegible]	1	
San Francisco	Mar. [illegible]16	1	
Colorado, Denver	Mar. [illegible]	[illegible]	
Illinois, [illegible]	Mar. [illegible]	[illegible]

THE TRAUMATISMS OF PREGNANCY.*

By DENSLOW LEWIS, M.D.,
CHICAGO.

PRESIDENT OF THE ATTENDING STAFF OF COOK COUNTY HOSPITAL,
CHICAGO.

A CONSISTENT consideration of the various injuries and accidents to which the genitalia of pregnant women are liable necessitates an attempt at definite nomenclature. Accidents are chance occurrences, of interest here only when detrimental in their effects. Injuries, in their relation to the conditions under consideration, are detrimental occurrences, often accidental, evidenced by structural changes, which may be microscopical in character, and which are occasioned by violence more or less pronounced. The term "traumatism" may very properly be used to designate the untoward effects of accidents or injuries. Traumatism is sometimes accidental, and usually injurious, but, under certain conditions, it is conservative. Although often used as a synonym for wound, it is susceptible of a wider and more generalized definition, or, at least, of a construction that will include microscopical lesions as well.

The different effects of traumatism require definition. A laceration is a solution of continuity of the soft parts, usually of limited extent, but sometimes extending to the peritoneum or bony confines of the pelvis. If the injury be produced by violence, often in the use of an instrument or other foreign body, the laceration may be multiple, and the destruction of tissue sufficient to warrant the term mutilation. Where laceration or mutilation of the vagina is sufficient to result in loss of tissue, the different fistulæ may result. The qualifications, complete and incomplete, are applied to injuries of the soft parts, and an extensive laceration is often called a rupture. This latter term, when applied to the uterus, may be complete or incomplete, and is also called external or internal in reference to its location. Specific terms are also in use, indicating not only the nature of the injury, but referring also to the etiology. There may be mentioned annular separation of the portio vaginalis, which signifies an amputation and a casting off of the parts; avulsion, which means a violent tearing away of a considerable portion of the uterus, and perforation, which I would define in reference, to the uterus, as that species of rupture produced by violence through the agency of a foreign body other than the child. It is described as internal or external, according to the starting point of the injury, and complete or incomplete, according to its extent.

The consideration of the traumatisms of pregnancy divides itself conveniently into a consideration of those injuries which are due to attempts at an interruption of the pregnancy and a consideration of injuries which occur incidentally, often by accident. I have elsewhere spoken of the facts regarding criminal abortion,[1] and have alluded to the tenacity with which, in spite of serious injury, the fecundated ovum may cling to its attachment once it is anchored to the uterine wall. I have also referred to those seemingly trivial accidents which suffice, sometimes weeks afterwards, to cause an interruption of the pregnancy.

A vaginal douche of hot water has caused abortion, and excited medico-legal interest in England, because it was not proved that the liquid used was noxious.[2] The use of an alum water injection has caused death,[3] and a bichloride douche has resulted in mercurial poisoning.[4] Death has occurred in consequence of intra-uterine injection of fluids, often undoubtedly because of the entrance of air into the circulation. Martin of Berlin mentions two cases of this character, and additional cases have occurred in this country.[5] Moreover, the instrument used has caused traumatism—in one instance causing a uterine perforation, which resulted in metroperitonitis and death.[6]

The use of foreign bodies to interrupt pregnancy has resulted in a great variety of injuries, as would be expected when it is remembered that the woman herself, or some ignorant midwife, is often the would-be abortionist, and that almost every conceivable appliance has been brought into requisition. Sometimes the uterus is not entered. Thomas reports a case where a physician's wife, thinking herself pregnant, passed an umbrella rib through the vaginal fornix, abdominal cavity and diaphragm, until it penetrated the right lung to the extent of two or three inches, in which position it was found at the autopsy.[7] In contrast to this case is one reported to the London Obstetrical Society, where a woman produced abortion on herself thirty-five times without injury by the use of a knitting-needle.[8] The foreign body may remain in the vagina without causing much inconvenience. On one occasion an elastic sound encircled the cervix, and was wound around it in a knot. It had been used to induce abortion, and remained in place afterwards for two years and a half, causing abdominal pain, especially during menstruation, until it was removed with forceps.[9]

When the uterus is entered, the results vary. Death has occurred simply from the introduction of a canula,[10] but often there is traumatism, which varies from a simple laceration to a complete internal perforation. Sometimes the injury heals unnoticed, but if infection occurs all the well-known sequelæ are possible. Among them I have observed a metastatic abscess of the brain, which was fatal, and in another case fourteen abscesses, which appeared on the legs and arms during a period of four months.

I append a record of some of the findings in septic cases: In the Tinkler case, a piece of wood produced the expulsion of a living fœtus; but at the autopsy there was found in the wall of the uterus evidences of injury consisting of numerous tears and perforations, which had resulted in gangrene.[11] In the case of a girl, sixteen years old, several punctures had been made in the anterior uterine wall by a knitting-needle or straightened hairpin. In the lateral wall was a large laceration, one and one-half inches long, made by a different instrument, and probably at a later period. The cervix was bruised, but not involved in the laceration of the body of the uterus, which latter traumatism probably caused death.[12] At the post mortem of a single woman, two months pregnant, who died four days after visiting an abortionist, there was found general icterus, foul discharge from the vagina and diphtheritic patches about the introitus. General diffuse purulent peritonitis, large soft spleen, gray liver, and other evidences of sepsis were present. Near the patulous os was a punctured wound, and higher up another one, half an inch deep, while at the fundus there was a rupture with sloughing edges, through which three fingers could pass.[13] In another case, where the woman was four and one-half months pregnant, death occurred within thirty hours. The cervix was lacerated; in the fundus uteri was a perforation of 4 to 5 cm., in which were engaged debris of placenta; in the peritoneal cavity was a large quantity of blood, partly coagulated, and there were signs of commencing inflammation.[14] Winter demonstrated two uteri; in one there was local gangrene of the posterior wall, to the extent of a five-mark piece. It was thought that the abortion was responsible for a laceration of this part of the uterus, and the acute gangrenous metritis had terminated in secondary perforation. In the other case the patient had died of diffuse septic peritonitis on the sixth day. Small collections of putrid pus were found between the intestines. The uterus was surrounded by encysted abscesses, containing a highly offensive matter and which filled the pelvis. Near the fundus, on the posterior wall, was a perforation, the size of a five-pfennig piece, with ragged edges, to some extent gangrenous. The difference in the two cases is thus explained. In this case the wall of the uterus was perforated and the virus was deposited directly in the peritoneal cavity, while in the former case the virus was apparently deposited on the uterine wall and resulted in a gangrenous peritonitis, which terminated in secondary perforation.[15]

---

*Read before the Medical Society of the State of New York, Albany, January 28, 1902.

It is unnecessary to cite other cases, for the effects of infection in criminal abortion are the usual ones. The traumatism, whether slight or extensive, is often the determining factor, for each solution of continuity in the soft parts becomes an additional door of entrance for pathogenic bacteria. Serious hemorrhage from injured bloodvessels has often resulted. One woman, six months pregnant, died twelve hours after consulting an abortionist. An enormous quantity of blood, partly coagulated, was found in the abdominal cavity. The posterior wall of the uterus showed an opening, of the diameter of an ordinary sound, extending to the right iliac artery, which was itself perforated a little below its origin. Three other punctures had their starting point in the cervix. In spite of these punctures, the fetus had not been reached; the membranes remained intact.[16]

The foreign body itself is often the cause of serious complications quite independent of the injury it may inflict or its instrumentality as a determining cause of infection. In addition to producing fatal hemorrhage by the puncture of a bloodvessel, or being the starting point of septic processes, an examination of the recorded cases shows that it passes through the uterus into the peritoneal cavity, or else it remains in the uterus or its tissues. In either event abortion may or may not occur. When the foreign body is retained, there may be no appreciable inconvenience, as in Bunge's case, where a needle was pushed into the internal os, and remained there twelve days after the abortion,[17] or suppuration may supervene, through the agency of which the foreign body may be expelled into the adjoining viscera, or penetrate neighboring tissues.

When the foreign body escapes into the peritoneal cavity, its fate is variable. My own case, so far as I know, was the first where a foreign body, introduced through a uterine perforation into the peritoneal cavity, was removed by abdominal section, an ovarian cyst and tube being removed at the same time, and the pregnancy continued without interruption until term. The case occurred thirteen years ago and was, in brief, as follows. A physician was endeavoring to produce abortion in a woman about three months pregnant by means of a silver male catheter. The patient was nervous and had suffered from melancholia. The point of the catheter was introduced within the uterus, when suddenly the woman made a convulsive movement, and the physician, to his horror, saw the catheter disappear. When I was called to the patient, some hours afterward, I recognized a uterine perforation of the posterior wall, through which I could pass a sound some 10 to 15 cm., but I could not feel the catheter within the abdominal cavity. An abdominal section was made, but nothing was discovered in the pelvis. Finally, the intestines were brought out of the abdominal cavity, and, after some little search, I found the catheter under the liver, and removed it. The uterine wound was closed with three sero-serous sutures, and the right tube and ovary were removed, together with a cyst about the size of a hen's egg. The patient made an uneventful recovery, and some six months later, after a normal labor, was delivered of a child, which is alive to-day.

Dr. Gill Wylie reports a case presenting certain points in common with mine. A girl inserted a glass rod into the uterus. It slipped beyond her reach, probably perforating the uterus. The following day the girl went to her work as typewriter. Some five weeks after that she aborted, and about two weeks after that time a tumor the size of an egg was felt in the left ovarian region. Celiotomy showed adhesions about the uterus and left ovary. This ovary and tube were removed, as well as the glass rod, which was found near the left kidney. No point of perforation was found. The patient made a good recovery.[18]

The literature of the past few years shows a number of similar cases where foreign bodies, which had entered the peritoneal cavity through a uterine perforation, were found at the autopsy, or were removed by abdominal section. A glass rod, for instance, is reported to have been removed from under the right kidney without interrupting the pregnancy, or causing much appreciable inconvenience.[19] In another case, at the autopsy of a young woman, three or four months pregnant, an irregularly-shaped hole was seen in the posterior wall of the uterus, and directly behind it, lying transversely in the pelvic cavity, was found a sea-tangle, or laminaria tent, about the size of a thumb.[20]

In place of perforating the uterus and passing through into the peritoneal cavity, the foreign body may remain in the uterus, causing various sequelæ, sometimes without inducing abortion. In one case a hard, irregular tumor filled the pelvis, extending into the right iliac region. A wooden spit, 12 cm. long, was removed from the uterus, where it had remained two years after an abortion.[21] A sinus over the sacrum, of six months' standing, was operated, and the following day pus escaped from the vagina. A bougie over six inches long, which had been introduced eleven months previously, and which induced abortion within two days, was removed from the uterus.[22] In another case a seton needle produced an abortion at three months but remained *in* *utero.* About a month afterward an abscess formed in the inguinal region, and on the seventy-fifth day the needle, six inches long, appeared at the surface.[23] I find record of an unusual case where a twig, six inches long, and as thick as a goose quill, remained in the pelvis five months without the patient's knowledge and finally penetrated the rectum.[24] The spindle of a spinning wheel was retained two years *in utero.* The patient was reduced and weak from the discharge which had become offensive to herself, her family, and all who approached her. The spindle was removed by two incisions in the cervix, and the patient recovered.[25] An abortionist introduced a catheter, and the patient pushed it in farther, until it disappeared. Two or three months later the patient complained of severe pain in the left thigh, hip and leg, and a large abscess formed near the left hip. A transverse bar was felt between the vagina and rectum, and was removed through the latter by means of forceps from a pouch extending to the lateral walls of the pelvis. It was the catheter which had passed through the posterior uterine wall, and had resulted in a phlegmon of the pelvis and perimetritis, giving rise to abscesses of the hip and perineum.[26]

As curiosities I instance two cases, where women produced abortion on themselves by forcing respectively a hairpin and a knitting-needle into the uterus through the abdominal wall. In one case, when a young girl left the hospital after being delivered of a dead fœtus at term, it was learned that she had forced a long hairpin through her navel to a great depth, with the avowed intention of destroying her child. She suffered great pain, which she concealed, and it was observed that some pus issued from her umbilicus after delivery. This discharge gradually ceased, and the patient left the hospital in good condition.[40] Another girl, six months pregnant, after failing to induce abortion by thrusting a knitting-needle through the vagina into the uterus, forced it through her umbilicus. Two days later abdominal section was performed and the tip of the needle was seen projecting from the fundus uteri. It was seized with forceps and removed, a stitch being inserted in the uterine puncture, as there was some hemorrhage. Two days later the patient miscarried and a black spot was seen on the child's buttocks, where apparently the needle had penetrated. The mother recovered.[41]

As regards treatment, these traumatisms of pregnancy may well be considered by themselves. They are due to a foreign body which has been introduced for the purpose of inducing abortion, and which has entered or remains in or about the uterus. In most instances the injuries produced interrupt pregnancy, and the dangers of a septic abortion are added to those of trauma. If the foreign body remains in the uterus, and especially if it projects through it, infection is liable to occur, and, if an abscess forms, it extends, as a rule, into the cellular tissue, pushing up the peritoneum in many instances, and pursuing, to a great extent, the course of other extraperitoneal pelvic abscesses. At times the infection is intrauterine and extends by continuity of epithelial surfaces to the fimbriated extremities of the tubes, and exceptionally beyond.

It is wise in every abortion to consider the possibility of its having been induced. It is important to understand that serious traumatism may have been ignorantly inflicted, and that the foreign body, probably not aseptic, may still be in the uterus or may have passed through it. A realization of this possibility, and a knowledge of the dire results that have followed different injuries, must modify our treatment in some important details. If the fœtal envelope be not injured and the condition of the patient be good, the case may often be let alone, unless the evidence of serious traumatism is plainly manifest, or it is probable that the foreign body is still retained or has entered the peritoneal cavity. Reasoning from the analogy of these cases of perforation to cases of rupture occurring at the time of labor, it is apparent that the first indication, after the arrest of hemorrhage, is to secure coaptation of the edges of the wound. This is accomplished, according to Fritsch, by pressure of the abdominal walls and counter-pressure of the floor of the pelvis.[27]

Vaginal douches should be avoided, swabbing out of the parts is unnecessary, and the use of drainage, except perhaps a small strip of gauze, is ill-advised. The perforation on the peritoneal surface is apt to be small, and the surfaces easily fall together. Should suppuration now occur, it will probably be without danger to the peritoneum.

In case the perforation be complicated by the presence of an incomplete abortion, it is desirable to secure the removal of the secundines without delay. I do not, however, sanction the frantic haste which some practitioners display in their efforts to empty the uterus. It is understood that the presence of membranes favors infection, but, after all, the danger is the infection itself. Moreover, it must be acknowledged that an exact knowledge of the extent of the injury is rarely possible, and that the use of the curette at this time is a real element of danger. Liebman of Trieste has demonstrated how easily a sound or curette passes through the uterus,[28] and nearly every gynecologist of experience can tell of instances in his individual practice where the uterus has been perforated. While it is true that statistics show that such an accident is rarely fatal, it need not be urged that it is most undesirable, and it is also true that the result is sometimes serious. Hoffman mentions a case where the omentum protruded at the os through an accidental perforation, necessitating a laparotomy and suture of the wound. This patient recovered.[29] Bratenahl speaks of removing a macerating fœtus at the third month. The small forceps used perforated the uterus and pulled a loop of intestine into the vagina. Abdominal section, performed an hour later, showed a quart of blood in the peritoneal cavity and a spurting artery at one side of the rent which was situated on the posterior and right surfaces of the uterus and was one and one-half inches long. The intestine was replaced and the uterine wound closed by deep and superficial sutures. The patient was well and at work in three weeks.[30] Kiwisch mentions a case where ileus occurred and an artificial anus formed in the uterus. For ten days fecal matter was discharged through the uterus, but the fistula then closed.[31]

If the fingers or the blunt curette can remove the secundines without inflicting additional injury, let it be done. Otherwise, I advise packing the uterus with strips of iodoform gauze, as Duehrssen first recommended.[32] An interval of twelve or twenty-four hours will allow of a partial separation of the decidua, often facilitating the removal of the secundines, but such interval will be of special value in permitting the peritoneal surfaces of the perforation to become agglutinated, thus diminishing the danger of infection of the peritoneum.

If the foreign body is within the uterus and accessible, it must be removed. If it has escaped into the tissues and become the starting-point for suppuration, the abscess, in most instances, will be easily reached through a vaginal incision, the foreign body will be removed and the abscess-cavity will be drained with iodoform gauze or rubber tubing. If the [illegible] [illegible] has extended upwards it may, in some instances, be more conveniently incised from above, near Poupart's ligament. The peritoneum, as is well known, is often displaced upwards in the [illegible] so that the suppuration in either case is practically extraperitoneal. In certain cases counter drainage will be advisable.

If the foreign body has escaped into the peritoneal cavity, a section should be made at once. On rare occasions the foreign body can be felt in the Douglas space and the section will be vaginal. In most cases the location of the foreign body is unknown, and the section must be abdominal, often of considerable extent, to permit a diligent search and, if necessary, a careful evisceration. In either event, unless sufficient time has elapsed since the perforation to allow the peritoneal surfaces to become agglutinated, the uterine wound should be closed. The effect, if any be unfavorable, of the presence of the foreign body within the peritoneal cavity should receive attention. Adhesions of uterus, tube, or ovary should be separated, and occasionally a resection or removal will be performed. Pregnancy is not a contraindication to the intraperitoneal surgery of pathologic conditions.[33] On the contrary, it often, in my judgment, makes imperative the advisability of resorting to operative measures.[34]

In certain cases of mutilation, of ulceration, or of septic infection involving a considerable portion of the uterine parenchyma, hysterectomy will be thought of. The indications for this operation during the puerperium I have elsewhere considered.[35] As regards traumatism in this connection no definite generalization can be made. It can only be said that if the injury is beyond repair, or if the danger of infection is deemed imminent, the uterus and perhaps its adnexæ as well should be removed. The same remark applies to injuries occurring late in pregnancy, often as a result of injudicious, unskilful, or ignorant attempts at delivery. The history of obstetric medicine in this connection offers a most dismal picture, since the days of Mauriceau. The entire uterine parenchyma has been torn out by manual interference.[36] A case of rupture of the vagina, extending into the right side of the uterus, presented no symptoms until the fourth day after labor, but terminated fatally on the tenth day from granular endometritis and diphtheritic exudate.[37] The injuries due to accidents and unskilled manipulations that occur in many fatal cases of operative interference are only exceptionally recorded. Portions of the uterus have been torn away and different instruments, introduced within the uterus for the purpose of effecting the delivery of the child or placenta, have penetrated the uterine wall, or have so mutilated the tissues that ulcerative perforation has occurred, or fatal hemorrhage has resulted as a consequence of an extension of infection into blood-vessels.

The traumatisms of pregnancy, due to direct or indirect violence, apart from attempts at the induction of abortion, are, as would be expected, most varied. It is to be remarked that an amount of violence sufficient to cause a fatal peritonitis, or to produce the most serious results, may not separate the connection between mother and child. At other times a slight injury suffices to interrupt pregnancy, it may be weeks after it has been inflicted.[38] Serious and, at times, fatal injuries occur as the result of severe, or apparently trivial, violence applied, as a rule, directly to the abdominal parietes. Such injuries are recorded as the result of falls, beating, lifting, jumping, crushing, kicks, and other forms of direct violence.

In one instance a woman eighty days pregnant fell from a wall ten or twelve feet high. She was found senseless half an hour afterward with blood issuing from her nose and ears. Five hours later she sank into complete coma, and death was momentarily expected. Fourteen hours after the accident she recovered consciousness, but complained of intense pain in the head, neck, and shoulders. On the tenth day she aborted, with the loss of about two ounces of blood, but without parturient pains, and two days later she resumed her usual occupations. Her pregnancy was twin, for seven months after the accident she was delivered of a boy at term.[39] In another case a woman about seven months pregnant slipped down a pair of stairs and struck astride the edge of an upright open barrel. She sustained an oblique fracture of the body of the left os pubis. A roller bandage was applied, opiates were administered, and the urine drawn for three days. In six weeks the patient could walk about. The labor at term was normal, but the fracture, we are informed, "of course reopened, and symptoms of peritonitis presented themselves, which yielded kindly to treatment and the patient recovered."[40]

Another woman pitched headlong downstairs, bruising herself considerably by the fall, but retaining sufficient consciousness to remount the steps to the room above, where she fell unconscious to the floor. She became feverish and flighty, and then became unconscious for five days. Miscarriage was expected, but did not occur. There was a gradual gain of consciousness. After the lapse of a month she was delivered of a child exhibiting no marks of injury, although it lived but twelve hours. The puerperal period passed satisfactorily until the third day, when she had a severe chill, followed by a rapid rise of temperature, accompanied by violent pain in the pelvis and the lower part of the abdomen. Local treatment caused improvement locally, but her general condition grew worse. Examination revealed an immense pelvic abscess, consequent, most likely, on cellulitis, and evidently pointing to the umbilicus, above which it extended on her left side. The whole pelvis was full of pus, which had pushed the uterus down until the vagina was almost obliterated. Poultices were ordered on the umbilicus, and a tonic containing iron was given. That night the abscess burst at the umbilicus, discharging large quantities of pus. There was improvement from that moment, which continued until the patient had completely recovered.[41]

A multipara at full term, while walking on the ice, fell and struck the anterior surface of the abdomen with the entire weight of her body, producing a sensation as if she were "split open." Fainting, amounting at intervals to complete syncope, followed. During the first twenty-four hours of the injury there was incessant vomiting, coldness of surface and extremities; the countenance was sunken and the aspect deathlike. There were occasional abdominal pains, but the os uteri was not in the least dilated. The external appearance of the abdomen was natural, but tender to the touch. Three days after the accident forced labor and delivery of child were resorted to, which required four to five hours. Profuse post-partum hemorrhage came on. The uterus not exhibiting the least contractile effort, the hand was introduced and immediately returned, detaching the placenta with facility, until it arrived at the upper and anterior portions of the uterus, where it met a resistance which seemed to be a perfectly firm adhesion of the placenta, extending over a surface of from four to five inches. This adhesion could not be broken with any prudent exertion. The patient was now much exhausted, and it was concluded that efforts to separate the detached mass from the adherent portion would be attended with most imminent danger. Death occurred six days after the accident. At the autopsy, sixteen hours later, gangrenous spots were to be seen on the inner surface of the parietes for four or five inches around the umbilicus. Some portions of peritoneum were adherent to the intestines, while other parts were softened in structure. Much fetid gas escaped from the cavity. A perfectly formed fœtus, in natural position, was found projecting from the uterus; the head and shoulders were lying closely upon the abdominal parietes, to which a portion of the placenta was adherent to the right and left of the umbilicus, extending downwards and laterally from three to four inches. The child was lying anterior to all the abdominal viscera. The intestines were mortified at various points. A rupture of the uterus occupied its anterior and superior portions, through which the child must have escaped with its own placenta at the time of the accident. A considerable quantity of serous fluid was found in the cavities.[44]

I also instance two other cases of fatal rupture of the uterus as the result of falls. In one case it will be observed the pregnancy continued until term—a period of two months—before the fatal effects of the injury became apparent.

A II-para, twenty years old, received a fall when in the seventh month of pregnancy, which, however, did not cause her much pain then nor afterwards. She went on to full term. After a restless night, with occasional slight uterine pains, she began to vomit. This was followed by pretty strong pains, during one of which she experienced a severe crack in the back, with a feeling of something suddenly giving way in her inside, which was immediately followed by a discharge of liquor amnii from the vagina. The os uteri was nearly closed, hard and incapable of admitting the end of the finger. There was a slight dark-brown discharge from the vagina, and death occurred two days later. At the autopsy a large rupture of the uterus, extending from the center of the fundus posteriorly along its whole length as far as the os uteri, was found. The opening was seven inches long. The uterus seemed to be perfectly healthy, and contracted over a firmly adherent placenta. The child had evidently been dead for some days, the first stages of putrefaction having set in.[45]

Veit showed the genitals of a forty-five-year-old IV.-para. When five months pregnant, she fell down, and with her abdomen struck the edge of a curb. Violent pains, vomiting and hemorrhage ensued. The patient was seen two days after the accident. There was vomiting, hemorrhage and discharge of pus. The cervical canal was penetrated with difficulty; there were shreds of decidua. The catheter went into the abdominal cavity. Celiotomy was performed. The fundus uteri was ruptured; the edges of the wound were suppurating. Death occurred in four hours.[46]

Smellie's case arouses the suspicion of ectopic gestation. A woman, four months pregnant, had a fall and three weeks later felt a load in her abdomen, which continued on the right side of the same for between two and three years. She then became pregnant again, and the child pressed so much upon the lump as to cause her great uneasiness. Three and one-fourth years after the accidental fall, she was delivered of a live child of full growth. From this time on she grew worse and worse, with violent pain above the umbilicus, and an inflamed tumor appeared near the part. Fomentations were used, which produced a suppuration at a small breach near the umbilicus. It continued discharging a fetid purulent matter for three or four months longer. A year or more after her last delivery she was suddenly seized in the night-time, and a hardened putrid mass of flesh, seemingly about eight inches long, was discharged through the old opening in her abdomen. The lump was rather thicker than a man's wrist, and, being opened, contained all the bones of a four-months' fœtus. At this time the woman was much emaciated, caused by the discharge of a large amount of pus from the wound, and, what was more extraordinary, whatever she ate or drank came out digested through the opening. She continued to discharge her excrement in this manner for six months, when it left her. After this the ulcer was kept open for six months more, when it dried of itself, with a very firm but small cicatrix. Nine months after the wound healed she was delivered of another child at full term, but with great difficulty. The bones of the fœtus lay in the woman's abdomen about four and a half years.[47]

Serious injury from falls has resulted where no direct violence was done to the abdominal walls. Reusing records a case where a young primipara, eight months pregnant, fell from a barn, four meters high. She lighted on her feet and sank down on her knees, but did not lose consciousness. Bimanual examination showed a contracted uterus and other symptoms, which warranted the diagnosis of rupture of the uterus and exit of the child into the abdominal cavity. Abdominal incision in the linea alba, about 15 cm. On opening the peritoneum a large quantity, consisting partly of fluid, partly of coagulated blood, intermixed with meconium and liquor amnii, escaped. The child, apparently in the eighth month of pregnancy, lay free in the abdominal cavity, and was extracted by the feet. The firmly-contracted uterus was taken out of the abdominal wound; it showed a long rupture, extending through the entire posterior surface of the fundus. The placenta was located in this rupture. While the uterus was compressed on the cervix, the placenta was extracted through the rupture, the membranes were also taken out, the somewhat ragged borders of the wound were smoothed, and the rupture was sutured through the entire substance of the uterus with nine sutures of silk. The abdominal cavity was carefully sponged, and the abdominal wound closed with silver wire sutures. Iodoform, plaster-of-Paris bandage; a thick drainage tube was introduced into the vagina and cervix up to the uterus. The hemorrhage was small during the operation, which lasted thirty-eight minutes. Drain was withdrawn on the sixth day. On the seventeenth day the patient was out of bed. On the twentieth day the bandage was changed and the sutures removed. On the twenty-third day she left the hospital in perfect health.[48]

A primipara, nineteen years old, when eight months pregnant, fell backwards on her shoulders and the upper part of her back from a loaded hay wagon, and at once experienced acute pains in the abdomen. Five hours after the fall her respiration was 36; her pulse was rather small and 106. The contracted uterus and large portions of the child could be felt around the umbilicus, separated from it and easily movable. An abdominal section was made. There was no free discharge in the abdominal cavity. The rupture extended through the whole posterior surface of the fundus uteri, then made a right-angled turn to the left and separated the fundus from the cervix for the distance of two and a half cm. From the uterine wound drainage was made through the vagina; the rupture was sutured [illegible] and the abdomen was closed. Convalescence was complicated by the breaking of the abdominal wound and the formation of an abscess. The patient was discharged in [illegible] weeks with an abdominal fistula, which eventually healed. Four years later the patient was again pregnant and delivered at term. On account of severe hemorrhage [illegible] the placenta a [illegible] portion of the uterus was necessary. The cicatrix was at the anterior surface of the uterus near the [illegible].[49]

A [illegible] IX-para, a week before term, was knocked down by a horse [illegible] and was struck by the front end of the car. There was a severe hemorrhage of [illegible]. Twenty-four hours later she was [illegible]. In the abdomen very large child parts were very distinct. The contraction [illegible] could not be felt. Internal examination showed the cervix preserved, the cervix admitting two fingers. Through the membranes a foot was felt. The child lay free in the abdominal cavity, the uterus had a large rupture, extending upward obliquely to the right and down to the left through the whole posterior surface of the fundus. The uterus was amputated according to Porro. Convalescence was complicated by fever and prostration but the patient finally recovered.[50]

A twenty-year-old primipara fell from a third story on the plaster pavement, alighting on the right half of the trunk, the right elbow and the knee. The patient was pulseless in agony. At the autopsy the child and placenta were found lying in the abdominal cavity under the liver. A penetrating rupture extended through the posterior wall of the fundus uteri and extended to the upper third of the uterine wall. Besides that there was an incomplete oblique tear of the cervix three centimeters long and an incomplete tear, eleven centimeters, of the fundus. In addition there were fracture of the skull and several fractures of the pelvic girdle.[51]

I append a case of traumatism from beating. A multipara thirty years old received a severe beating when five and a half months pregnant. On examination a few superficial excoriations were found on the face and ecchymoses of abdomen over the right iliac fossa. The uterus was about two and a half inches beneath the umbilicus. The patient had not yet noticed the movements of the child. No fœtal nor uterine sound could be heard; there was no issuing of any kind from the vulva. The cervix was [illegible] soft and velvety, the os transverse and admitted the end of the finger. The patient complained of pain over the seat of ecchymosis, but this pain seemed superficial. She was ordered rest in bed and friction with camphorated oil over the hypogastrium. She came to the hospital on the 9th and left on the 15th. She had a normal delivery at term.[52]

I find a case of traumatism of the uterus from lifting which I here submit. A XVI-para, thirty-four years old, while lifting a heavy load was suddenly seized with abdominal pain and other symptoms. Treatment was instituted for acute peritonitis. The fœtus had not been felt since the accident. A guarded stylet was passed into the upper and posterior part of the uterus, where the membranes were punctured, giving exit to a large quantity of extremely fetid gas and some yellowish brown liquor amnii, which continued to drain away, followed in ten hours by the expulsion of a fœtus of, apparently, seven months utero-gestation, in an advanced stage of decomposition. The placenta and parts were much softened and speedily expelled. There was no hemorrhage, the vomiting ceased, and in six weeks the patient had recovered.

Accidental rupture of the uterus has occurred from exertion while pumping. This strain differs little if at all from the conditions present when lifting. A woman, thirty-five years old, five months pregnant, while in the act of pumping from a pump, the handle of which was suspended higher than usual, so that she was obliged to use considerable exertion in order to raise the water, suddenly experienced a strange sensation in her abdomen, accompanied with fainting, so that she was compelled to go to bed. Very soon afterwards she was taken unwell with a great deal of pain and soreness, which continued with very little variation for nearly a week. Six weeks afterwards a doctor was called. He considered it probable that premature labor was about to commence and ordered rest and castor oil. In the evening of the following day the patient complained of pain of a sharp and stabbing character in the left hypochondrium, like that of costal rheumatism. The next day a vaginal examination was made, but not the slightest dilatation nor discharge was observed. The os was as small and rigidly contracted as in a virgin. Five days later there occurred uterine hemorrhage and slight labor pains which lasted for thirty hours. The fœtus could be felt distinctly on external examination, the whole abdomen seemed to be enlarged, and the child appeared to lie transversely across it, principally above the umbilicus. Five days after this labor came on and a fœtus was extracted with the vectis. The placenta was adherent, and, in separating it with the fingers a portion was found elongated and extending back to a perforation, the edges of which were contracted and tense, barely of sufficient size to admit the index more than half-way. At the end of a week the patient had recovered, but the fœtus could be felt as before. Ten months afterwards she miscarried at five months and a hard, irregular mass was felt above the uterus about the size of a fœtal head. It was believed to be the escaped fœtus of her former pregnancy, now partially ossified.[53]

The crushing traumatisms recorded vary in severity according to the extent of the injury. A woman, thirty-eight years old, and near term, was crushed with very considerable force between the hinder end of the shaft of a cart and a wall, the shaft striking her on the right side of the uterus, her left side being towards the wall. There was great abdominal pain, profuse hemorrhage from the vagina, frequent vomiting and weak pulse, about 125. When she was seen there were no external marks of violence, but a considerable amount of effused fluid in the lower part of the abdomen. The os uteri was closed. No part of the child could be felt and hemorrhage now was very slight. A grain of opium every hour was ordered. The next day the fœtus was recognized free in the abdominal cavity by external palpation. Forcing open the uterus under chloroform, a transverse rupture was apparent towards the back and right side. Abdominal section permitted an easy removal of child and placenta. The abdominal incision was closed with wire, but the patient died sixty hours after the accident and thirty hours after the operation.[54]

A young Irish woman, in the sixth month of pregnancy, was crushed between the parapet of a bridge and the wheel of a large dray bearing an iron fly-wheel weighing twenty tons. The lower part of the abdomen and the pelvis were compressed within a space of two inches in the antero-posterior diameter. At the moment of the accident she had a gush of blood from the vagina. When seen, her pulse was slow and scarcely perceptible, and occasional rigors occurred. The surface of the body was cold and the patient complained of being chilly, but especially of an intense pain about her hips and the lower part of the abdomen, where, about two inches above the symphysis pubis, was seen a transverse bluish mark about three inches long and one inch wide. The abdomen was very tender in the hypogastric region. The right iliac bone was easily movable and appeared to be separated from the sacral bone. In front, about midway between the symphysis pubis and the anterior superior spine of the ilium, there was a fracture through the horizontal ramus of the pubis. The line of fracture was felt or indicated by pain, on pressure in the vagina, but the pain caused by examination was so extreme that it was made only cursorily. About the sixth month of pregnancy the uterus appeared to be normal, and the child's head could be easily distinguished. The os uteri admitted the end of the finger, but the plug of pregnancy still remained firm. Eight hours afterwards she was delirious and continued in a desperate condition for four days, but, to the surprise of her attendant, she then began to improve, and within two weeks could get around with a cane. The right iliac bone remained about one inch higher than the left. The right side of the pelvis was flatter than the left. Three months after the accident the fœtus and membranes protruded from the vagina. They were carefully removed by means of the funis, and a small hard placenta was extracted. The uterus contracted feebly, and some oozing of blood continued for some hours afterwards, so much so as to cause her to faint, but it stopped on the administration of ergot. She said that she had felt only two or three slight pains before the fœtus was expelled. Within two and one-half months afterwards she was able to walk one and one-half miles up-hill and down again. The fœtus was between five and six months, much wrinkled from long maceration, but presenting no marks of injury. The placenta was very firm and solid. Twelve months afterwards the patient was taken in labor at full term. After she had been in labor thirty-six hours, a physician who knew nothing of the previous fracture applied forceps and extracted a dead child. The patient died one hour afterwards.[55]

I now append a case of rupture of the uterus in consequence of a kick. An XI-para, aged thirty-seven years, who had had no miscarriages and all of whose previous labors had been normal, with the vertex presenting in every case, was, in the evening of July 11, 1890, when her labor was nearly due, violently kicked in the right groin by her drunken husband, who was wearing heavy hobnailed boots. She became sick and faint and was in considerable pain throughout the night. Twelve hours after the assault labor came on. Everything progressed well until 9 P. M., when she complained of considerable tearing pain in the lower abdomen, accompanied by a sensation of faintness. Soon afterwards the pain became less frequent. There was an extensive bruise in the right groin. The patient was in a cold sweat, her face was ashen-colored; her pulse was small but regular and about 130 per minute. The breech was presenting and lying on the perineum. At intervals very feeble pains occurred, which had no effect on the presenting part. Delivery was effected as rapidly as possible by passing a silk handkerchief over the right thigh by means of a copper wire. Extraction was quite easy. A nearly transverse rent, anterior in the genital canal, was found. Several loops of intestines could be distinctly made out. At the autopsy the abdomen was enormously distended; there was a well-marked emphysema of the abdominal wall and subperitoneal tissue. More than two quarts of blood, in a fluid state with clot, were removed from the posterior culdesac. The uterus showed an oblique tear four and one-half inches long anteriorly and to the right through the lower segment. The rupture through the tissue was complete. Elsewhere the uterine tissues were healthy. It was concluded that the kick had lacerated the uterine fibers, and that complete rupture had ensued with the labor.[65]

The spleen has been ruptured by a kick. Savor records a case where splenectomy was performed during the sixth month of pregnancy and the patient went on to full term without incident.[85]

I append a case where a woman, six months pregnant, was tossed by a cow. The horn struck her with much violence midway between the umbilicus and the pubis. Five or six hours after the accident the fœtal movements had ceased, but the uterine souffle was pretty distinct in the neighborhood of the injury. There was also an enormous circumscribed tumor, tender to the touch. The abdomen was remarkably tender and tympanitic, but there was no vomiting. A pill of one grain each of calomel and opium was given every second hour. Four weeks afterwards the patient miscarried suddenly. An abscess formed in the abdominal wall, discharging sanious fluid of intolerable fetor. A large putrid, fleshy mass was removed and the wound finally closed, leaving, however, a large ventral hernia, which was kept closed by a bandage, so that the patient was later on delivered of another child without any bad symptoms.[57]

The traumatism inflicted by external violence during pregnancy is at times evidenced by wounds—often penetrating—either of the abdominal walls or the external or internal genitals. They have occurred from falls and other accidents, as well as the result of injury due to gunshot, knife, pitchfork, nail, or cattle-horn. I instance cases of each variety:

A woman, five months pregnant, sustained a severe wound, one-half inch deep, on the internal surface of the left nymphas. Three quarts of blood were lost, but finally the hemorrhage was controlled by folds of linen, wet with cold water and applied within and without the vulva. Premonitory labor pains set in the next day and continued for four hours. Laudanum and hyoscyamus were given, and the patient went on to full term.[58]

In another instance the hemorrhage was fatal, although the wound was limited in extent. The patient, three or four months pregnant, fell over a chair, causing a laceration of the vagina, extending through the mucous and submucous tissues and exposing a plexus of veins, three of which were found to be divided.[59] A third case showed a more serious injury, the left nympha being torn across and the external genitals being much bruised. This woman also fell across the chair and there immediately gushed forth blood and liquor amnii. She was eight months pregnant. The abdomen, we are told, was quite soft after the accident, but filled up slowly in a few days, and the wound finally healed perfectly. Two and a half months later a healthy child was born. It was noticed, when the membranes were ruptured, that a very large quantity of water escaped, followed by a great deal of hemorrhage.[60]

There is a record of a fatal rupture of the vagina with hematocele produced by a fall. As the woman, near term, was about to sit down, her little son had pulled away the chair and she fell to the floor. For ten days she flowed until she became faint, nauseated, extremely pale, covered with a cold perspiration and possessed of feeble pulse. A dead child was born by forced delivery, but the woman died soon afterwards. At the junction of the vagina and uterus was a rupture—a round, ragged hole as large as a half dollar, from which extended a large hematocele. Blood was found in the abdominal cavity.[61]

When there occurs a penetrating wound of the abdominal wall the prognosis is often grave because there is a greater likelihood of infection, while hernial complications and possible intestinal injury may add to the seriousness of the accident. A woman, five and one-half months pregnant, fell into a well, at the bottom of which were masons' tools. She received an enormous wound, extending obliquely, in the form of a circle, from the right flank to the left iliac fossa and including the right iliac region as well as the hypogastric region. The wound was 3 cm. deep, but was not penetrating. It cicatrized in thirteen days. The next day the patient died of cholera. The egg was found intact, the membranes everywhere unruptured, and the uterus healthy.[62]

Another woman, near term, fell in a dark cellar while carrying empty bottles in her arms. She received serious wounds in different parts of the body and a penetrating wound, two inches above the umbilicus, through which protruded omentum, small intestine and transverse colon, forming a mass the size of a man's head. This hernia was reduced and the abdominal wound closed with five sutures. Ice dressing was applied and opium was given. Labor pains started up the same day, and the woman was safely delivered of a healthy boy. She suffered from sepsis for two months, but finally recovered. The abdominal wound healed in seven days.[63]

Penetrating knife wounds of the abdominal wall during pregnancy and of the pregnant uterus vary from a simple puncture to a true Cæsarean section—often self-inflicted. In the former case pregnancy appears to exert no effect on the prognosis, and in the latter the fœtus is often injured by the same violence which causes the traumatism of the uterus. A drunken husband stabbed his wife, who was near term, with a penknife in the left side. An omental hernia protruded; it was ligated, and the sixth day it fell off and the wound healed kindly. The woman was delivered at term without incident. Since then she has had two more children.[64] I cite a case where uterine perforation occurred by a knife-stab entering the sciatic notch and extending through the pregnant uterus into the fœtus. The patient, eight months pregnant, received a knife stab in the left buttock. There was considerable hemorrhage, a sensation of numbness throughout the lower part of the body, but no pain. The next day she was delivered of a dead child, which showed on the left parietal and near the median suture a sharp incision involving the integuments and extending to the bone, which was scratched, but not perforated. There was total insensibility of the sole of the foot and of the external border of the foot up to the last three toes. In fifteen days the patient was up and the wound had nearly cicatrized. An abscess formed on the foot, and numbness, anæsthesia and pains along the outer border of the leg and back of the toes persisted for seven months.[65] In Laborie's case a wide knife-blade penetrated the uterus through the abdominal wall and evacuated amniotic fluid. Ten hours afterwards the woman, who was five and one-half months pregnant, aborted. Grave symptoms of prostration without symptoms of peritonitis appeared. Death occurred two days after the stab wound. The anterior superior part of the uterus had a small perforation, also slight traces of peritoneal inflammation.[66]

The cases of self-inflicted Cæsarean section are most remarkable and show a wonderful tolerance to traumatism on the part of the pregnant uterus. A woman in Italy cut through her abdominal wall to the extent of four and three-fourths inches, killed the fœtus by wounds in the chest and abdomen before extracting it, and finished by cutting off its head. She recovered completely in forty-eight days.[67] A seamstress, between six and seven months pregnant, received a knife wound near the umbilicus through which protruded both feet of the fœtus and about a yard of small intestine. The patient was seen seven hours after the receipt of the injury. The temperature was normal, the pulse frequent but not small, and her condition fair. The intestines were uninjured. The uterine wound was enlarged to facilitate the extraction of the fœtal head. The opening in the uterus was transverse between the cornua but the placenta was not wounded. The uterine incision was closed with twelve catgut sutures and the abdominal wound with ten metallic ones. Death occurred from peritonitis in four and one-half days. There were abundant intestinal adhesions and some seropurulent fluid in the abdominal cavity, but the uterine and abdominal wounds were freely united, and the condition of the uterine cavity was normal.[68]

There are cases in which the penetrating wound was accidental and made by other agencies than a knife.

A healthy woman, aged twenty-seven years, pregnant five and a half months, holding the handle of a two-pronged fork in her hands, was chasing a cow. She fell to the ground, stumbled over the pronged end, forcing one tine into her abdomen and uterus through the edge of the placenta and into the lower angle of the left shoulder-blade of the fœtus. The fork entered about two and three-quarter inches above the pubes, near the external border of the right rectus muscle, and its withdrawal was followed by an evacuation of liquor amnii, slightly streaked with blood. Four days later she gave birth, without special hemorrhage, to a dead male fœtus, which presented by the breech. After a serious illness the patient recovered. The wound of the abdomen became fistulous and did not close for four months. An abscess opened into it and discharged freely, also a small fecal fistula developed, through which currant seeds, gas and fluid having a fecal odor escaped. This fecal fistula did not make its appearance until eighteen days after the accident and followed an attack of diarrhœa lasting over two days. The uterine wound is believed to have healed in a few days.[69] A woman, seven months pregnant, was pierced by a long, large and square nail, attached to the backboard of a wagon. It entered the abdomen to the left of the umbilicus, penetrated the uterus and wounded the child. At the time the woman experienced only slight pain. Water mixed with blood escaped at once through the wound in a jet. The patient had the courage to return home on foot. The wound was narrow and would not admit the little finger. A mixture of blood and water was escaping from it. The uterus was contracted, rigid and painful to pressure. Cæsarean section was proposed but rejected. At the end of fifteen hours the wound ceased to flow. Then supervened general disorder, convulsions, a sort of momentary catalepsy and a burning thirst. Sleep was disturbed by dreams, grinding of the teeth, and a foamy agitation of the lower jaw. The patient's eyes were haggard and pale, her pulse small and concentrated; there supervened hiccough and vomiting, accompanied by a discharge of green bile. Death occurred sixty hours after the accident. At the autopsy it was found that the hole in the skin did not correspond with that in the uterus. The latter was two inches above it, and was remarkable only on account of an inflammatory, very thick tumor; it scarcely permitted the introduction of a stylet, being so narrowed through contraction. In the uterus was a considerable quantity of water; but there was neither a bloody flow nor clots. More resistance was presented by the orifice than by the body of the uterus. The child had been reached by the nail in the middle of the right subspinous fossa of the scapula. The puncture, although very small, had caused an ecchymosis, which extended from the shoulder to the nates.[90]

The subject of cattle-horn lacerations has been exhaustively considered by that indefatigable worker, the late R. B. Harris of Philadelphia. He instances twenty cases of cattle-horn perforation of the abdomen in pregnant women. In two cases particulars, as regards the extent of the injury, are unknown. In six cases the uterus was uninjured and the victims recovered. In one case the uterus is described as bruised, also resulting in recovery. In another case the perforation was not complete, and the wound healed by granulation. In four cases different portions of the fœtus protruded. Here the fœtus was removed through the abdominal wound, in three cases by enlarging the uterine wound sufficiently to permit of its escape. These three cases recovered. In the fourth case a dead fœtus was delivered *per vias naturales*. The woman recovered, but died from hemorrhage following a subsequent pregnancy. The autopsy showed blood in the abdominal cavity, but no rupture of the uterine cicatrix is reported. In six cases the fœtus was expelled through the perforation, which varied in length from five inches to the distance from one ischium to the other. Of these cases three recovered. The patient in one instance sewed her own abdomen.[71]

The cases of gunshot wounds are of interest. Where the uterus is not entered, the pregnancy usually goes on without incident. Even when the bullet perforates the uterus, it does not necessarily result in an interruption of the pregnancy unless the fœtus is killed. The important facts in relation to eight cases are appended:

CASE I.—Stage of pregnancy, six months. Shot in abdominal cavity, on line from left nipple to anterior superior spine of right ilium, three inches from ensiform cartilage, passing upwards. Bullet lodged in lung, at posterior border of serratus magnus. Result to fœtus, none. Result to mother, perfect female fœtus sixteen weeks afterwards; recovery. Treatment not stated.[72]

CASE II.—Stage of pregnancy, six months. Shot four inches to the right and on a line with umbilicus. Fate of bullet not stated. Result to fœtus: Bullet wound behind acromion process of right scapula; another above umbilicus; right leg shattered below knee. Result to mother: Abortion next day. Discharged fully recovered four weeks later. Treatment: Celiotomy. Uterine wound closed with three Lembert sutures; two drainage tubes. Abdominal wound closed with wire sutures.[73]

CASE III.—Stage of pregnancy, five months. Shot to the right and a little below the umbilicus. Bullet not found. Fœtus uninjured. Result to mother: Labor fourteen days later. Recovery on twelfth day. Treatment: Celiotomy six hours later showed wound in anterior uterine wall, which was sutured.[74]

CASE IV.—Stage of pregnancy, nine months. Bullet entered uterus. Living child born. Bullet had passed through arm and chin of fœtus. Death in eight hours. Result to mother: Labor imminent; twelve hours later, delivery. Recovered, with slight symptoms of traumatism. Treatment not stated.[75]

CASE V.—Stage of pregnancy not stated. Probably near term. Bullet entered uterus. Fœtus living; bullet, size of pea, near right clavicle, subsequently extracted. Result to mother: Labor at once. Recovered, but wounded in shoulder, side and hip. No treatment.[76]

CASE VI.—Stage of pregnancy, near full term. Wounded two inches above right ilium, back of anterior superior spinous process, bullet passing downward and inwards into fœtus. Fœtus dead. Bullet entered body. Result to mother: Delivery forty hours afterwards. Some shock. Recovery No treatment.[77]

CASE VII.—Stage of pregnancy, six months. Wounded two inches above anterior superior spinous process of ilium, upwards through uterus and fœtus; bullet lodged somewhere in back, but was not found. Fœtus dead. Bullet entered below left scapula, ranged diagonally through the trunk, and escaped by the right hip. Result to mother: Labor within twenty-four hours; severe peritonitis; recovery. No treatment.[78]

CASE VIII.—Stage of pregnancy, four to five months. Wounded in umbilical region, four fingers' breadth from the median line. Fate of bullet not stated. Five intestinal wounds; wound of fundus uteri, through which a loop of funis protruded. Fœtus uninjured. Result to mother: Abortion the following day. Complete recovery. Treatment: Resection of 20 cm. of bowel. Loop of funis resected. Stump returned within uterus. Abdominal incision quickly closed.[79]

The pregnant uterus has been often injured during the course of some peritoneal operation. I cite three cases: In operating upon an ovarian cyst, the trocar punctured a three months' pregnant uterus two inches from the fundus to the depth of two inches. The cyst was then removed and the patient recovered. Five weeks afterwards severe hemorrhage occurred and a decomposed fœtal body was separated from the head, the latter coming away the following day. The patient recovered.[80]

A patient, thirty-four years of age, had a large abdominal tumor, which had been noticed for about four months, and was bilobular; the left lobe, the size of an orange, was fluctuating; the right lobe was less distinctly fluctuating, and extended as high as the hypochondrium, being apparently inseparable from the uterus, the neck of which was small. There was complete amenorrhea. Pregnancy was at first suspected, but this diagnosis was afterwards rejected. The trocar was introduced into the left lobe, and about thirteen ounces of slightly albuminous fluid was withdrawn. A second puncture gave exit to a reddish, gelatinous fluid. A diagnosis of cystic sarcoma was then made, and an operation decided upon. Celiotomy was performed. One lobe punctured discovered a fœtal head. The other lobe, the real tumor, having chocolate-colored contents, was then removed, and the uterine wound closed with sutures. Reproduction of amniotic fluid occurred. Labor took place twenty-four hours afterwards, presenting nothing abnormal. Recovery was slow, but complete.[81] An unmarried woman, aged twenty-three, was operated upon for an ovarian cyst without previous vaginal examination, which she objected to. A second tumor posterior to the cyst was punctured with the trocar. It proved to be the pregnant uterus. The incision was enlarged, and exposed the placenta, which was separated and removed. The breech was seized and drawn toward the opening, when the fœtus was expelled by uterine contractions. The membranes and liquor amnii were not removed. It was a gestation of seven and a half months. The uterine incision was closed by interrupted sutures passing through the visceral peritoneal muscular wall and mucous membrane. The os uteri was dilated to give exit to the lochia and a flexible catheter was introduced for some hours. The patient of the [illegible] entered. The sutures were brought out at the lower angle of the wound and left long enough to hang down between the thighs. The patient recovered and was never told of the pregnancy.[27]

The treatment of this class of traumatisms occurring during pregnancy depends not alone upon the conditions of the injury as they are apparent, but also, and perhaps especially, upon the recognition of possible sequels of a serious character, which are often due to infection. In many of the injuries to the external surface of the uterus where women are kicked in the abdomen and otherwise suffer traumatisms of the pelvic viscera, there is often a laceration of the peritoneal surface amounting at times to a separation of the peritoneum from the underlying tissues. The effused blood may be absorbed and the peritoneal surfaces may be agglutinated, even if the injury is an external perforation. If the muscular tissue beneath the peritoneum is injured, there often forms a blood-cyst, which may push off the peritoneum for a considerable distance. There is also danger of subperitoneal emphysema in the anterior surface of the uterus, with a possibility of air breaking through into the abdominal cavity.[23] Moreover, the exact extent of the injury cannot always be determined at the time of its infliction without subjecting the patient to a critical examination, which usually necessitates an abdominal section.

In my judgment, the interests of the patient are more often conserved by such a procedure than by trusting to chance. It is well known that serious hemorrhage may occur within the abdominal cavity without manifesting itself by pathognomonic symptoms until too late. Cases on record show that intestinal rupture and other serious traumatism may present no untoward symptoms until infection has supervened and the patient's life is jeopardized. It is true that if the patient is first seen several days after the accident, peritoneal surfaces may have become agglutinated, effusion may have subsided, and a watchful expectancy may be sufficient. Each case must be treated on its merits, but it must be realized that traumatism sufficient to fracture pelvic bones or cause extreme shock, acute anæmia, rapid pulse, or other undue symptoms, is likely to have produced some serious internal injury which must be sought for. If none is found, it cannot be said that an abdominal section as performed to-day will have added materially to the risk.

With an open abdominal wound the extent of the traumatism should be accurately determined, the wound should be sufficiently enlarged, if necessary, to permit a thorough examination of all intrapelvic viscera. Injuries of intestines and omentum should be repaired by closure of lacerations or perforations and, if necessary, by resection. The details of a modern abdominal section will be carried out in the usual aseptic manner and all injuries of different viscera will receive proper attention. If the peritoneal surface of the uterus alone is injured, the hemorrhage may be controlled by forceps or ligature, and the peritoneal edges may be brought together by Lembert sutures. Should the muscular tissue be perforated as well, interrupted buried sutures should coapt the torn fibers and the peritoneal surfaces should be united by separate sutures, as in Cæsarean section. Should a portion of the fetus protrude from the perforation, it will be advisable to complete its removal through the uterine wall, even if the uterine wound must be enlarged. The removal of the placenta occurs preferably by the vagina, but if the os is not dilated, or if the placenta is detached and perhaps protruding through the uterine wound, it should be removed together with the membranes in the same manner as the fetus. The operation is now practically a Cæsarean section, and will be treated in accordance with the operator's views regarding that operation. In the absence of pelvic deformity, or an extensive injury which might favor infection, the Sänger technique may well be followed. Should the patient be in extremis, the wound septic, or in the opinion of the operator likely to become so, the probabilities not great for the [illegible] of perfect repair, it is preferable to remove the entire uterus, as was performed in a case of rupture by Prevost et Moreau.[24]

The presence of a foreign body, usually a bullet, modifies the treatment but slightly. If found it will, of course, be removed. Should it have entered the uterus beyond the reach of the operator and no point of exit be discovered, its presence may be disregarded and the details of treatment may be applied as already indicated. If the bullet has entered the child, premature delivery will probably ensue with the possibility of a simultaneous expulsion of the foreign body. Should this not occur, the foreign body may be extracted later, or it may become encysted in the uterine wall without inconvenience, as so often occurs in other parts of the body.

A CLINICAL REPORT RELATING TO (*a*) HEMORRHAGE PERSISTING NOTWITHSTANDING CURETTAGE, AND (*b*) SECONDARY HEMORRHAGE FOLLOWING ABDOMINAL SECTION.*

By EGBERT H. GRANDIN, M.D.,

NEW YORK.

GYNECOLOGIST TO THE COLUMBUS HOSPITAL.

I shall limit my remarks to the conditions specified in the title, for the reason that I desire chiefly to provoke discussion, and the less time I consume, the more will remain for those who favor me with their criticism.

Uterine hemorrhage is suggestive of three cardinal conditions: (1) Either there is something in the uterus requiring removal; (2) There exists disease of the uterus; or (3) There is present an extra-uterine condition demanding careful scrutiny and often speedy operation. To exemplify these premises, I record the following cases:

Case I.—I was requested, recently, to see a lady who, notwithstanding thorough curettage for menorrhagia, was flowing profusely. Owing to the hyperæsthesia of the patient, I was unable to determine more than that the uterus was not enlarged, the cervix was closed, and that there lay in front of the uterus a tense mass of uncertain character. My request for examination under anæsthesia met with ready response, and I determined the mass to be the enlarged Fallopian tube. The woman's pulse was not accelerated, and there was absence of temperature rise. The family physician informed me that at the time of the curettage he had not found this mass. I advised an exploratory abdominal section, giving it as my opinion that there might exist an ectopic gestation, even though the subjective symptoms of the condition were absent. Within a week, I was requested by a colleague to assist him at an abdominal section, and found this same woman, who had drifted away from her family physician, and had employed another. A day or so previously she had had an attack of abdominal pain, and the pulse was slightly accelerated. Under anæsthesia, I determined that the mass in front of the uterus was less elastic, and I ventured a diagnosis of ruptured ectopic gestation. On section clots and blood were found in the peritoneal cavity emanating from the ruptured right Fallopian tube, which lay in front of the uterus. Examination after removal confirmed the diagnosis of ectopic pregnancy.

This case certifies the position which I have maintained in papers and in discussions for years, that the symptomatology of ectopic gestation is very unreliable, and emphasizes the necessity of most careful examination of every woman who complains of uterine hemorrhage, especially where the bleeding persists notwithstanding curetting.

Case II.—About five years ago I saw, in consultation, an exceedingly exsanguinated young married woman, who had been curetted three weeks previously for metrorrhagia following a suppositious miscarriage at six weeks. Notwithstanding the curettage, the hemorrhage had continued, and intrauterine packing, and the application of astringents locally, and the administration of ergot and cotton root having failed, I was sent for to make a diagnosis on a woman in the very jaws of death—for it has rarely been my fortune to see such an exsanguinated woman live. The pulse was barely perceptible; the mucous membranes were absolutely colorless.

---

*Read before the Section on Obstetrics and Gynecology, New York Academy of Medicine, March 27, 1902.

Under stimulation I managed to secure sufficient reaction to justify the removal of the woman to a private hospital, where she was quickly anesthetized. Exploratory curettage was negative, and vaginal hysterectomy was quickly performed as the sole remaining means of checking the hemorrhage. For days thereafter the woman hovered on the verge of death, but finally convalesced. On section of the uterus a vascular nodule was found at the left uterine cornu, and this was the causal factor of the hemorrhage. Unfortunately, the specimen was lost before it could be subjected to examination, but I have little doubt but that I was dealing with a deciduoma malignum, a condition which, at the time I am speaking of, was not discussed as much as of late.

Case III.—Recently, at the General Memorial Hospital, I had referred to me a lady who had been thoroughly curetted and yet was suffering from metrorrhagia. The uterus was slightly enlarged, there was a history of malignant disease in the family, both appendages were enlarged and adherent. Consent was secured for the performance of radical operation under anesthesia if such be deemed wise. Exploratory curettage simply proved that my predecessor had curetted the uterus well. On opening the abdomen the diseased adherent appendages were removed, and after duly weighing the fact that nothing to explain the metrorrhagia had been found, hysterectomy was performed. On section of the uterus a nodule of a vascular type was found, and this is being examined by Dr. W. S. Stone. I fancy that his report will be *deciduoma malignum*. But even if he do not I should not regret the hysterectomy, for the reason that both appendages having been removed for disease and the double curettage having yielded negative result from a diagnostic and curative standpoint, the uterus was not alone a useless organ but one open to suspicion.

These cases call for no comment at my hands beyond the statement that rarely will such a radical measure as hysterectomy be required to control hemorrhage from the uterus, but nevertheless the instances are extremely suggestive as reminding you and others that this recently described disease—*deciduoma*—occurs, possibly, with greater frequency than we have hitherto fancied.

The second subdivision of my paper deals with secondary hemorrhage after abdominal section—a very rare occurrence nowadays in view of the betterment in our technique towards the securing of hemostasis. There is absolutely no complication following abdominal section which can give more concern and which offers the greatest ground for indecision—indecision which can have but one outcome where it prevails, and this outcome the death of the patient. At the very outset I wish to protest against the use of the word shock as unscientific, as a mere cloak for either ignorance or timidity. Let us remember once and for all that after an abdominal operation the symptomatology of shock is radically different from that offered by intraperitoneal hemorrhage, and let us further remember that when death ensues the use of the word *shock*, while it may satisfy our conscience, falls far short of desirable scientific exactness, to say the least. Bear in mind that I am referring to symptomatology occurring after an abdominal section which has been elective, and where, in consequence, the patient has been carefully prepared after the manner with which you are all so familiar. There is a vast difference between such a case and the victim of a railroad accident, for example, or a patient suffering from the effects of the rupture of an abdominal or pelvic viscus, as a further example. The symptoms to which the term *shock* may be applied after a predetermined abdominal section are evanescent in character and yield to proper stimulation; the symptomatology of slow intraperitoneal bleeding is progressive and can have but one ultimate issue if we satisfy our minds with the term *shock* and fold our hands in complacency. The pallor of the surface, the cold and the clammy body, the extremely rapid pulse and the high temperature the result of paralysis, so to speak, of the heat center—these signs differ absolutely from the rapidly increasing pulse, the anxious facies, the gradually progressive pallor of the mucous membranes, the sighing respiration, the increased elevation of temperature at the abdominal surface apparent to the *touch*—symptoms of internal hemorrhage. I yet recall a life sacrificed to indecision some fifteen years ago, because I, together with colleagues, was satisfied with calling that condition *shock* which after death was found to be *intraperitoneal hemorrhage*, and until recently I have had no occasion to put into practise a vow registered at the time, that in any future case with the like symptomatology I should reopen the abdomen at the risk of finding absence of hemorrhage rather than pinning my faith to problematical shock as an explanation, which under the given conditions, never explained anything. I would reiterate to-night that which I have repeatedly stated: *After an elective abdominal section the word shock means hemorrhage.*

Finally, let me state that to-day there exists no ground for indecision, for if we dread—and naturally so—the reopening of the abdominal incision we may at least make our diagnosis with absolute certitude by playing the trump card when in doubt, and this card is an exploratory vaginal section—something which may be performed for diagnostic purposes with the minimum disturbance of the patient and, indeed, where need be without anæsthesia. The diagnosis established, abdominal section follows as a *sine qua non*.

In my own work I have seen three cases of secondary hemorrhage following abdominal section. The first case I have referred to above, and the woman died because I did not know enough to save her. And yet it should be remembered that it is not such a simple matter to be able to make up our minds in time for reoperation to be of utility. In memory of the fact, however, that it is, as a rule, within the twenty-four hours following abdominal section that the type of secondary hemorrhage, which alone is to be discussed to-night, occurs, the point I desire to impress is that where the symptoms are obscure it is wiser to explore through the culdesac than to dally. The two cases which I proceed to report were plain enough, certainly the second case in which the diagnosis was made for me, but the rule I have laid down for myself for future guidance is that which I have impressed above.

Case IV.—Salvatore T. entered my service at the Columbus Hospital on December 5, 1901. In March of the same year I had opened her abdomen, performed plastic work on her right ovary, had punctured some cysts in the left ovary, and had suspended the uterus to the parietal peritoneum.

She re-entered the hospital complaining of pain in the left side of the abdomen. Examination revealed disease of the appendages on the left side and I reopened her on December 20, 1901. Left salpingo-oophorectomy was performed, the broad ligament being transfixed and the appendages doubly ligated with medium catgut prepared in the hospital; her pulse after operation was 84 and her rectal temperature was normal. At 7:30 that evening the pulse rate was 122, the temperature 100. At 6 A. M. the next morning the pulse was 128 and the temperature 98°. At 10 A.M. the pulse had risen to 130. A hypodermatic injection of morphia of one-quarter of a grain—a most valuable means of differentiating shock—had no effect on the pulse, which steadily rose to 134. The caliber was good, however, since she had been freely stimulated. I saw her at two in the afternoon, and the *elevation of the abdominal surface temperature* made me suspicious that internal hemorrhage was progressing. There was no pallor, but the facies was anxious and the respiration markedly accelerated. I reopened the abdomen and evacuated a large number of clots. On bringing the pedicle into view I found the ligature *in situ*, but the catgut had frayed and active hemorrhage was progressing. I religated, filled the abdomen with salt solution, and closed by through and through silk-worm gut sutures. The woman rapidly reacted and was discharged about the twenty-first day.

CASE V.—Feti G., entered the Columbus Hospital November 26, 1901. At the time of operation, on November 29, her pulse was 76 and her temperature 98°. She was curetted, the left appendages were removed, and the uterus was suspended by the parietal peritoneum. The tube was exsected and the broad ligament was quilted with medium catgut. The abdominal incision was sewed in layers with catgut. At 7 P.M., the operation having been completed at 2:30, the pulse rate was 96. At 1 A.M., November 30, the pulse was 118, the temperature 100°. At 6 A.M. the pulse had risen to 122. At 11 A.M. the house officer notified me that the abdominal dressings were stained with blood, and that, notwithstanding stimulation, the pulse was steadily rising and losing force. At 2 P.M. I saw the woman, took down the dressings and found the entire incision gaping and clots and intestines protruding. She was transferred to the operating room, anæsthetized, the broad ligament was drawn up and a similar condition existed there as in the abdominal incision; that is to say, the catgut had frayed out. The broad ligament was again ligated, the peritoneal cavity filled with hot saline solution and the abdominal incision closed by through and through silk-worm gut sutures. The woman convalesced. The case is recorded rather as showing the wonderful toleration certain women possess than as a record of intraperitoneal hemorrhage diagnosticated. The diagnosis, indeed, was made for me by nature—or rather by poor catgut.

CASE VI.—This case is recorded here as an instance of so-called *shock* where the symptomatology suggested internal hemorrhage, but where the use of morphia enabled me to exclude the latter condition.

Maria A. entered the Columbus Hospital January 2, 1902, On January 10 double salpingo-oophorectomy was performed at 2 P.M. At 4 P.M. the pulse was 104. At 6 A.M., January 11, the pulse was 122 and the temperature was 99°. At 9:30 the pulse was 134, the temperature 99°, and the respiration 22. At noon the pulse was 140, the temperature 101°, and the respiration 30; the surface of the body was cold; the pallor of the face was intensified, but the mucous membranes were red. On telephonic notification I instructed my house officer to stimulate freely and to give one-quarter of a grain of morphia hypodermatically. At 2 P.M. I saw the woman and the pulse had dropped to 120 and the temperature to 100°. From this time on the pulse rapidly fell to normal and the woman convalesced.

These cases require no comment. The point I desire to bring out in discussion is as to whether it is your opinion that a statement made not so long ago by an operator of experience be true, that the symptomatology of internal hemorrhage occurring within twenty-four hours after abdominal section is not sufficiently exact to warrant us in reopening the abdomen. My own feeling in the matter is exactly the reverse, and, furthermore, I desire to contend that vaginal section will always enable us to settle this question which is of vital moment to the patient and to our reputation. At the outset, however, it is essential that we should free our minds of the thought of that bug-bear shock, remembering that the symptomatology is essentially different and that the free use of morphia ought to make the differential diagnosis for us. I have purposely refrained from commenting on technique, and I grant that in private practise, or rather in house operating, it is not always feasible to act with the energy which is at our disposal in a hospital. It is essential to limit the discussion along the lines I have specified, otherwise the main object of my appearing here—the securing of expression of opinion as to the symptomatology of so-called shock and of intraperitoneal hemorrhage—will be defeated.

36 EAST FIFTY-EIGHTH STREET.

GENERAL TREATMENT OF MEASLES.*

By LOUIS FISCHER, M.D.,
NEW YORK.
ATTENDING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS, ETC.

THE treatment of measles can best be divided into (1) Hygienic; (2) Medicinal; and (3) Dietetic.

The Hygienic Treatment consists in guarding the child from unnecessary exposure to the extremes of heat or cold. It is unnecessary to have the sick chamber too warm. The same is also true regarding extra clothing. The proper way is to have the temperature of the room no less than 70°F., and no more than 76°F. The surface of the body should be well protected with a covering of either flannel or woolen. To keep children in a room at a temperature of 90°F., as we frequently see them, is unscientific and positively harmful. Such patients suffer from excessive perspiration, and are certainly more prone to the chilling of the surface of the body and consequent complications, such as pneumonia and similar catarrhal troubles.

They should be placed in bed with their back to the light. In this manner the glare of the sunlight will not be permitted to strike their eyes. When possible, red shades should be used to screen the sun's rays. It is unnecessary to place them in dark rooms. At the Children's Hospital in Berlin I have frequently gone through the measles wards and found the above-mentioned conditions. There appeared far less eye trouble and far less complications where a good current of air was permitted and where also the entrance of sufficient light was allowed. Quiet and rest are of prime importance. All discharges, be they from the nose, eyes, or ears, and all expectorated matter should be thoroughly disinfected by the use of one to two-thousand solution of bichloride of mercury. Very mild solutions of permanganate of potassium or boracic acid serve the purpose of irrigating the ear and nose and for washing the mouth.

---

*Read, by invitation, before the Society of the Alumni of the City (Charity) Hospital, March 12, 1902.

The above general rules can be well applied in almost every instance. In special cases special rules must be applied, then, if unfavorable conditions prevail, it will sometimes be necessary to individualize.

The Preeruptive Stage.—During the period of incubation certain drugs will be necessary to hasten the development of the eruption.

If there is no hyperthermia then mild diaphoretic treatment will be indicated. Warm demulcent drinks, hot teas, containing some lemon or orange juice, will be advisable. Spirits of Mindererus in half-dram or dram doses can be given at intervals of one to two hours until diaphoresis is produced. If the temperature is below 102° F. no further drug treatment may be required. The valuable point is to watch the stomach and bowels, hence stimulation of the emunctories will be urgently demanded in the preeruptive condition. All the functions of the body must be carefully watched.

Antipyretic Treatment.—Tincture of aconite, in one-drop doses, will be found serviceable in addition to spirits of mindererus. My method is to combine the aconite with the diaphoretic when it is necessary to have both an antipyretic and a diaphoretic effect. Great care should be exercised in dealing with very weak or rickety children or with those in whom severe cerebral symptoms exist. In the latter cases treatment should be directed towards preventing convulsions by hot mustard foot-baths and the like. They can be aided in their action by applying an ice bag or ice-cold cloths to the top of the head. When severe nervous symptoms, such as twitching or insomnia, exist, bromide of sodium in five or ten grain doses by mouth will be well borne. The mustard foot-bath is especially valuable where stupor or somnolence exists in the prodromal stage.

When vomiting is encountered a wise plan is to give the stomach rest. The discontinuance of feeding and medication for half a dozen hours, or even longer, may be the means of allaying severe gastric irritability. During these intervals of rest for the stomach we can resort to rectal alimentation, as well as to rectal medication. A cleansing enema followed in about ten minutes by the injection of an ounce or two of peptonized milk with an equal quantity of starch water will be easily absorbed. If necessary, we can repeat this form of rectal feeding in three or four hours and can substitute it with the yolk of one or two eggs and peptonized milk. It is well to remember that the rectum merely absorbs the food but does not digest it, hence, to properly aid nature, the food injected should be thoroughly peptonized. Medication, when given per rectum, can best be administered in small suppositories. If the bowels be irrigated an hour before the suppository is inserted, the food or nourishment will be more readily retained and absorbed.

One of the most frequent causes of death, next to pulmonary complications, is intestinal catarrh. Knowing this to be the case, great care must be exercised in the use of purgatives. Phosphate of sodium, in ten to thirty-grain doses, dissolved in a little water, is a very useful laxative; so also are small doses, a tablespoonful or several teaspoonfuls, of citrate of magnesia. Not only is the latter very useful to quench thirst, but it is also a mild aperient, and, owing to the citric acid which it contains, it stimulates the action of the kidneys. Very small doses of calomel may also be given, 1-10 of a grain two or three times a day, depending on the urgency and requirements of the case.

Water should be given very liberally. I frequently add fruit juice to it, such as that of lemon, orange, or unfermented grape juice.

The Relief of Cough During the Course of Normal Measles.—When the nose and the pharynx discharge freely and irritate the child, then irrigation with some bland antiseptic, such as a one per cent. boric acid solution, will be useful. If, however, we are dealing with a catarrh involving the nose and throat as well as the bronchial mucous membrane, then the accumulated viscid secretion if very annoying can be discharged by giving an emetic. Most children cough and swallow their expectoration. For the relief of this condition a dose of castor oil will be most useful. In older children who can cough and expectorate, an emetic is contraindicated. The compound syrup of squills, in doses of a teaspoonful, repeated every half hour until vomiting is produced, is serviceable. Syrup of ipecac in dram doses, repeated every half hour, is another valuable remedy. When, however, emesis is not produced by giving either of the foregoing remedies, I have found the mineral emetics very prompt in their action and very serviceable.

My choice of drugs is sulphate of copper, in half-grain or one-grain doses, repeated every half hour until vomiting occurs. It is best administered in one or two teaspoonfuls of warm water.

When the cough is very distressing, especially at night, steam impregnated with eucalyptus or oil of thyme will be useful. Steam seems to loosen the viscid mucus which accumulates in the bronchial tubes. Continued cough at night and day will not only disturb the child's sleep, but will exhaust the patient and prevent convalescence. It is, therefore, wise to administer small doses of codeine, 1-20 to 1-12 grain, depending on the age and the strength of the little one. This is to be repeated every two or three hours if the cough is troublesome. Two or three grain doses of chloral hydrate for a child two to three years old, and a smaller dose for younger children, may be given to produce sleep.

Heroin is a drug that has been extensively recommended by many writers for the relief of cough in adults. I cannot recall a single instance where this drug has served me. I have seen marked cardiac depression, and in one case, in consultation with Dr. J. H. Wurthman of this city, there was a distinct evidence of collapse. The child appeared to be suffering from a coma, although a very small dose of the drug had been administered. It may have been that some idiosyncrasies existed in these cases, but nevertheless on general principles it is wise to be careful when we meet conditions resembling collapse, due to deficient heart action.

Malt extract, given for the relief of cough, is a very favorite preparation. It certainly relieves, and in addition thereto is nutritious, and, lastly, has a laxative effect. A teaspoonful given several times a day is taken very eagerly and is certainly of value.

Pneumonia Complicating Measles.—When lobar pneumonia or when lobular pneumonia complicates measles, symptomatic treatment is indicated. Hyperpyrexia may require active treatment, such as tepid sponging, or a local application of a tepid pack. Cold baths and cold packs do not seem to be as well borne as in other eruptive diseases. If, however, pneumonia is not of an abnormal febrile type, an oiled silk jacket, enveloping the whole thorax and applied next to the skin, is very valuable.

For the relief of dyspnœa, several dry cups applied posteriorly, are useful. If the dyspnœa recurs and relief has been afforded by the previous dry cupping, the same treatment may be renewed.

Antipneumococcic serum has been used by me in but one case in which the temperature was 104° F, the pulse 160, and the respiration 80 per minute. The disease ran a regular course, crisis appeared on the eighth day, in spite of the injection of a small bottle containing 10 c.c. of this serum. It is hardly necessary to state that no conclusions can be drawn from the injection of this serum in this particular case. The child made a perfect recovery, though I do not believe any credit for it can be given to the serum.

Diphtheria Complicating Measles.—When diphtheria complicates measles the usual form of treatment of the diphtheria is required. This should be instituted independently of the measles. The point worth noting is that there is such an œdema of the glottis during the course of measles that it frequently leads to laryngeal stenosis. Intubation should not be resorted to unless there is no other means of relief. More lives are lost in spite of intubation during the course of measles than in any other form of laryngeal stenosis. It is here that continued steam inhalations and emetics will be found useful.

Antitoxine, so valuable in the treatment of diphtheria, is certainly to be considered the moment we find the slightest evidence of a diphtheritic type. I must not be misunderstood, however, as advocating the use of antitoxine in the treatment of catarrhal laryngitis which so frequently complicates measles and which may be a non-diphtheritic condition. A great many physicians use antitoxine in immunizing doses during the course of measles to prevent a possible diphtheria. This measure I regard as altogether too radical. When, however, typical symptoms of diphtheria, with clinical evidences of the same, are present, a healing dose of two or three thousand units should be injected, depending on the age and strength of the child. This generally suffices to destroy existing toxæmic conditions.

Dietetic Treatment.—If a nursling is affected, breast milk is the only form of diet. If a bottle baby is affected, the greatest care must be exercised in the feeding, owing to the subnormal condition of its stomach. The moment gastric symptoms, such as vomiting or diarrhœa or anorexia are marked, a greater interval between the feeding period should be given. In addition thereto, a smaller quantity of food should be administered. If, for example, an infant, while in health, receives a six-ounce bottle of milk, it is wise to give but four ounces, or even three ounces, according to its appetite.

When violent gastric symptoms prevail, in spite of all precautions, absolute rest of the stomach must be enjoined. In the interim, rectal feeding may be necessary to sustain life until the gastric irritability has passed away. In older children, who have taken milk for thirst, buttermilk may be substituted with advantage. Buttermilk has a very laxative effect; it will also quench thirst and is very nutritious. Concentrated food, such as cream and butter, owing to their nutritious character, should be administered. Thus, a small quantity of cream rather than a large quantity of milk, if the stomach will tolerate it, will be beneficial. Soups, broths, eggs, and paps, of oatmeal and milk and farina and milk, are indicated. In older children, calf's-foot jelly, chicken jelly, raw-scraped steak, and oysters, in addition to broths and milk and cream, may be allowed. Fruit and fruit juices may be given *ad libitum.*

The convalescence of the patient, and the restoration of the body to its normal state, will depend on the nutrition rather than on the amount of drugs poured into the body. Subnormal conditions must be restored to their normal state. Insist on feeding per mouth if possible, per rectum when necessary, and then, and then only, can we hope for the resolution of what I consider one of the most dangerous of infantile diseases.

65 EAST NINETIETH STREET, NEW YORK CITY.

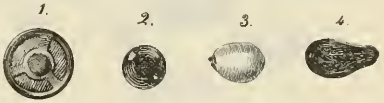
RHINOLITHS AND FOREIGN BODIES IN THE NOSE.

By J. M. INGERSOLL, A.M., M.D.,
CLEVELAND, OHIO.

FOREIGN bodies may enter the nose through the anterior or posterior openings, or through the sides of the nose and face. In the latter case the foreign bodies are usually pieces of metal or some other hard substance which are acidentally hurled against the side of the head with force enough to penetrate the nasal cavities. Such cases are generally treated surgically soon after the accident. Foreign bodies which enter the posterior nares may consist of any substance which has passed through the mouth and is then forced through the nasopharynx into the nose by the act of vomiting or coughing. Frequently, the easiest way to remove such a substance is to push it back into the nasopharynx, taking care that it does not fall into the trachea.

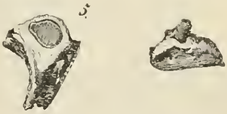
By far the largest number of cases of foreign bodies in the nose occur in children, who put all sorts of things in their own and each other's noses. The following list of articles which I have removed serves to illustrate the diversity of character of such bodies:

A shoe-button from the right nasal fossa of a five-year-old girl; a bean from a four-year-old boy; a piece of cardboard from a five-year-old girl; a watermelon seed from a four-year-old girl; a small cloak button from a five-year-old girl; a piece of bone from a pig's foot which a two-year-old boy had pushed into his nose. This child was sitting at the table with his mother when the family were eating chopped pig's feet, and had put one of the pieces of bone into his nose.



Foreign bodies removed from the nasal fossæ of children.

A piece of chopped pig's feet.



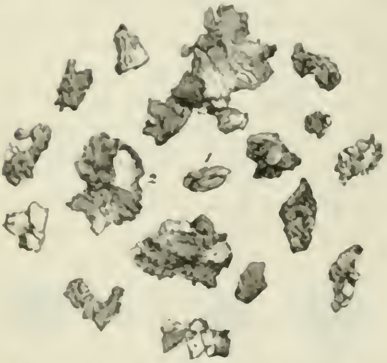
Rhinolith, in which the nucleus was a pea.

1.—Cloak button. 2.—Shoe button. 3.—Bean. 4.—Watermelon seed. 5.—Section through the smaller rhinolith, showing the nucleus, a pea, in place. (Scale ⅝ actual size.)

The symptoms of a foreign body in the nose are a unilateral discharge, at first serous, then purulent or mucopurulent, occasionally tinged with blood if there is much irritation and ulceration. Nasal obstruction develops on account of the irritation and swelling of the surrounding tissue, and the voice shows the typical nasal twang. Facial neuralgia or pain may be present if the body remains long in the nose, or if it is a substance which will absorb moisture and swell, such as a bean, thus causing pressure. The diagnosis is usually easy; the foreign body can either be seen by direct inspection or felt with a probe. If the foreign body has been in the nose a long time, it may be partially or even completely hidden by granulation tissue, but careful probing will locate it.

In removing a foreign body from a child's nose, a little chloroform should be given; in the case of an adult, cocaine anæsthesia is usually sufficient. The application of adrenalin solution prevents hemorrhage and gives one a clear field for operation and also contracts the surrounding tissues and thus facilitates the removal of the body. Ordinarily the foreign body can be grasped with a pair of forceps and easily removed. If it is imbedded in granulation tissue, it may be necessary to pass a probe under it and elevate it, and then grasp it with the forceps.

Undue haste in removing foreign bodies is never justifiable, for they may remain in the nose several days or even weeks without causing much inconvenience. If they are allowed to remain in the nose a long time, the salts from the nasal secretion may be deposited around them, forming a rhinolith or nasal calculus. Such calculi may also form around inspissated secretion, and a few cases have been reported in which no nucleus could be discovered.



Rhinolith weighed 2 grams. In the center No. 1 is a shriveled bean, the nucleus. On the left No. 2 is the piece which contained the bean. (The picture is about ¾ the actual size.)

They may grow in concentric lamellæ, or by irregular concretion, when they look very much like a piece of ordinary sandstone.

The report of the following case of rhinolith is of interest mainly on account of the size of the stone, and of the nucleus, a bean, around which the rhinolith was formed.

The patient was a well-developed man, forty-six years old. He said that for thirty years or more the left nasal fossa had been obstructed. During this time he had consulted several physicians, none of whom had examined his nose, but informed him that he had "catarrh," and had prescribed a nasal wash, which had not had any appreciable effect on the rhinolith.

Externally, the left side of the nose appeared broadened, as the left nasal bone was pushed somewhat forward and upward. The left eye was inflamed and its tear-duct was obstructed. The septum deviated to the left, making a rather large right fossa, which was otherwise normal. The left vestibule was nearly filled by an irregular, jagged projection of the rhinolith, which extended down to the integument, and made it impossible to examine the left fossa. Posterior rhinoscopy showed that the rhinolith extended backwards as far as the end of the inferior turbinal.

On account of the difficulty anticipated in cocainizing around the rhinolith, I advised the crushing and removing of the stone under a general anæsthetic, but the patient preferred to have it removed under cocaine anæsthesia. Accordingly, I cocainized around the rhinolith, as far back as possible, and broke off and removed several pieces. The hemorrhage was quite free, so that I waited a few days and then repeated the operation, removing at that time the piece which contained the bean. In the specimen can be seen the piece which contained the bean, and from which the rest of the rhinolith grew.

While I was crushing and removing one of the large pieces, a rough edge broke through the palate into the mouth, making a tear about one centimeter long, that healed by first intention. In four sittings I removed the whole stone, which weighed two grams.

The turbinals in the left fossa were atrophied by the pressure, and the mucous membrane was inflamed and ulcerated. The ulceration healed rapidly after the removal of the rhinolith, and the patient has since had no more trouble with his nose. This rhinolith grew by irregular concretions extending completely through the fossa and filling most of the inferior and middle meatuses. When I showed the patient the piece containing the bean, he said that he remembered putting a bean in his nose when he was a boy; this bean had evidently remained in the nose and became the nucleus of the rhinolith.

Recently I removed a much smaller rhinolith from the left nasal fossa of a young lady. She complained of facial neuralgia on the left side, and a persistent discharge from the left nostril, which had been troubling her for several years. On three or four occasions, after blowing her nose forcibly, she had found some small pieces of stone in her handkerchief and wondered where they came from.

Inspection of the nose showed the left fossa obstructed by hypertrophied and inflamed tissue, covered with a mucopurulent discharge. With a probe, the rhinolith could be felt in the posterior half of the inferior meatus. After cocainizing, I grasped it with forceps and tried to remove it through the anterior nares, but it was wedged under the inferior turbinal and would not come through, so I pushed it into the nasopharynx comparatively easily.

This patient had no remembrance of any foreign body being put into her nose, but a section through the rhinolith shows that its nucleus was a pea.

These specimens have not been examined chemically, but I suppose that they are composed mostly of the salts of calcium and magnesium, as these salts predominate in rhinoliths.

The Treatment of Neuralgia with Castor Oil.—F. E. Waxham reports several cases of a severe nature, in which this remedy brought about a speedy cure. It should be given in doses of from one to two ounces three or four times daily, although in some cases good results have been obtained with smaller doses. After the first two or three doses, it usually loses its cathartic effects. We should guard against its too free cathartic action by sufficient doses of opium in some form, as it is the constitutional and not the local effect we desire. It is best given (after having been thoroughly washed, and a few drops of some aromatic essence added) either in milk with effervescing seltzer or in ale, especially Bass' ale. A palatable mixture can be made by combining the oil with mucilage of acacia and lime water. It should be thoroughly shaken before giving. It may also be given in hot lemonade. The author urges the trial of this simple remedy, which has given results in neuralgia never before obtained by other medicines.—*The Colorado Medical Journal*, December 1901.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

VOCATION AND LONGEVITY.

THE effect of employment upon man's span of life is, in the nature of things, very great. It can be easily understood that factory work, and particularly of a certain kind, such as match-making, working in copper, lead or zinc, needle-making and various other kindred trades, saps the constitutions of the laborers and brings them to an early grave.

Again, there is no cause for wonder that clerks, and, indeed, all those who are compelled to lead a sedentary life, often in unsanitary surroundings and with a paucity of out-door exercise, fail to reach by many years the average period of life obtained by their more fortunate brethren.

A consideration of the tables of occupational mortality of those which are termed the higher classes, will, however, occasion some surprise among persons who have disregarded the matter.

Dr. Arlidge, an English physician, has recently published the results of years of close study of of the subject, quoted in the Chicago *Tribune*, and his conclusions are instructive and valuable. Dr. Arlidge has decided that the indolent rich are the shortest lived of all classes, and gives as the cause of this seeming anomaly that they worry their lives away. Doing nothing, or existing without a definite and serious aim in life, leads inevitably to a constant round of so-called pleasure, but which is really nerve-racking labor of the most wearing kind, known as "killing time." The man of means and of leisure becomes sated with amusement, and finally life to him is not worth living. Of course, all the rich do not come under this category, and Dr. Arlidge excepts the philanthropists who have a purpose, and the rich traveller who has his diversions, but the gilded youth, who lavishly squanders nature's best gifts, soon finds that he has killed his zest for enjoyment, and he either dies of pure ennui, or literally burns himself out.

The farmer stands at the head of the list of long livers, he generally has to toil hard, but his work is in the open air, and in an altogether healthy environment. Good digestion with him waits upon appetite, and he eats heartily of wholesome food, which nourishes his frame and makes good red blood. The dissipation and vices of cities are unknown to him, although he has his innocent pleasures, and, above all, he is a man with an object in life.

Next in order of longevity are the clerical, legal and medical professions.

The clergyman in the country leads a life somewhat closely resembling that of the farmer, he is much out of doors, his hours are necessarily regular, and he is precluded by the nature of his calling from dissipated habits of a worldly sort.

The lawyer's lines, so far as health is concerned, are not cast in such pleasant places. His life is a more strenuous one, generally full of excitement, with the brain kept for most of the time at high pressure, and the nerves on the strain.

Of the three learned professions, the physician can calculate on the shortest life. A conscientious doctor must of necessity be the most self-abnegating of men; and, as a rule, he has little or no time to think of himself, as his mind is continually burdened with the responsibilities of his practice. In both town and country the medical man is compelled perforce to live under unnatural conditions; he is out in all weathers and at all times, and it may be truly said that a busy physician can hardly call an hour his own. Then he is constantly exposed to infection, and a large part of his life is spent in the depressing and devitalizing atmosphere of the sick room. It, therefore, will be no matter for surprise to learn that, excepting artists, the largest number of suicides are recorded among members of the medical profession. Insanity, also, has wrecked the minds of many brilliant physicians.

Politics, according to Dr. Arlidge, is one of the most healthy of occupations. This fact has been proved time and again—Gladstone, Beaconsfield, Bismarck and Thiers are conspicuous examples of the truth of this statement. Great brain workers are notoriously long lived, and among literary men, scientists, professors and teachers, the mortality if far lower than among the industrial classes. Therefore Dr. Arlidge holds that activity of the mind, if bent in the right direction, has more to do with the health of the body than muscular exertion, but he thinks that a judicious combination of both forms of exercise brings about the ideal condition.

Employers of labor are especially subject to heart affections. Nervous complaints come second, apoplexy third, and consumption fourth.

The commercial traveller is a man who seldom reaches the allotted term of years. Irregular hours, too much drinking and smoking, and poorly cooked food are the factors that tend to bring his existence to an untimely end.

Policemen are, as a class, very healthy and live to an advanced age, due to the fact that they are chosen for their soundness, and that their life is largely spent in the open air. Rheumatism is the affection with which the policeman is chiefly troubled. The mail-carrier is healthy on account of his outdoor life, but for the same reason is peculiarly subject to rheumatism.

The miner, nothwithstanding that for eight hours of the twenty-four he is working cramped in a coal pit, shut out from the sun and in an atmosphere thickly impregnated with coal dust, is, contrary, to preconceived notions, a healthy man and usually lives to a green old age.

Figures such as collected by Dr. Arlidge are not only curiously interesting, but provide most valuable data for the compilation of sanitary statistics from which boards of health and public health services may gather useful hints as to the best means of improving the condition of the industrial classes among whom the mortality is greatest.

REPORT OF INDIAN PLAGUE COMMISSION.

The *Edinburgh Medical Journal* contains a second account by Dr. Sutherland of the report of the Indian Plague Commission.

As regards restrictions of the movements of travel, etc., in epidemics, the Commission concludes: "That any system of land quarantine imposed with the object of detaining passengers from infected areas either at a point where the infected and uninfected areas join or at different places within the infected area, has not been found in practice to prevent the spread of plague. That any system of medical examination on railways which falls short of keeping travelers under detention for the ordinary period of incubation must be defective. That it appears to be unnecessary to medically examine people traveling between places in an infected area. That the disinfection of personal effects of travelers by railways should not be attempted."

Respecting the mode in which rats become infected, the commission think that infection through the alimentary canal cannot be common. The experimental work done by Gibson, Hankin, and Simond has all led to negative results. As to inoculation through the skin, their results differ somewhat from those of the German and Austrian Plague Commissions, and are thus stated: "We, ourselves, found that it was in all cases necessary to inoculate a very sensible quantity of plague culture in order to insure the death of the animal, and in some cases we found evidence of great resisting powers on the part of the rats with which we had to deal in Bombay."

Respecting the agency of suctorial insects in the spread of plague, the commission is skeptical with regard to Dr. Simond's well known views on the subject, and think that the evidence brought forward by him in support of his theory is by no means convincing.

The causes concerned in the spread of plague in infected places the Commission state to be as follows: (1) Human agency, including infected clothes or merchandise carried about by man; (2) Rats.

Discussing the rat question and plague, the Commission say: "(1) In some places where severe epidemics have occurred among men, rats have not been infected at all, and in many places where there have been plague epidemics among men the disease has not appeared among rats in epidemic form; (2) Occasionally, where there has been considerable mortality among rats, there has been an absence of plague among men; (3) Even when there has been the largest amount of plague among rats, the risk to the persons coming in contact with them appears not to have approached that undergone by persons inhabiting houses in which there have been plague patients or persons coming into contact with pneumonic plague; there are, however, cases where a very considerable number of plague cases in a village has been directly attributable to an epidemic among rats; (4) Seeing that the excreta of rats may be deposited anywhere through a house, and that the number of rats which are infected may many times exceed the number of men who are infected, a severe epidemic among rats, must, we think, tend considerably to the spread of infection; (5) When plague is once established in a place we have no doubt that human agency is a more important factor in spreading the disease than the agency of rats."

The views of the President of the Commission on the effects of overcrowding and bad ventilation in disseminating the plague may be expressed as follows: (1) The intensity of the disease and its great fatality are largely dependent on the pollution of the air in the dwellings; (2) The cause of this pollution is not only overcrowding, but the absence or insufficiency of means of ventilation and overcrowding; (3) That overcrowding is chiefly operative by adding to the air pollution; (4) The increase of moisture and the elevation of the temperature, the increase of carbonic acid, and the diminution in the amount of oxygen in the atmosphere, together with the deficiency of light, stimulate the growth and increase the virulence of any plague bacilli that may be present, and, at the same time, predispose the occupants to attack by plague. Preventive measures recommended by the Commission's President are simple, and follow naturally from his views as to spread of disease: (1) Each room should be provided with a window for the admission of air and light; (2) Each house and its immediate surroundings should be kept reasonably free from all causes of air pollution.

The most interesting part of the Commission's report is that which refers to the propagation of plague by unsanitary surroundings. The members of the Commission, and especially its president, do not appear to have been impressed with unhygienic conditions *per se* as a fruitful cause of spreading the disease, but are of the opinion that a dirty state of, and polluted air in, the house itself are chiefly responsible for disseminating plague.

Nevertheless, there can be but little doubt that the pest flourishes most widely and most virulently in those places where filth prevails.

The Commission's views with regard to the spread of plague by insects agrees in the main with those expressed by Nuttall, that no definite proof has been as yet forthcoming that fleas or other suctorial insects take a prominent part in this respect.

In the absence of any specific remedy, our efforts to prevent the spread of the plague would seem to rest almost wholly upon insuring a plentiful supply of fresh, pure air, and by keeping dwelling houses and their immediate vicinity as clean and wholesome as circumstances will permit.

SUDDEN BLANCHING OF HUMAN HAIR.

Numerous cases have been recorded in which the hair of a person who has undergone some violent emotion—sudden shock to the nervous system, generally caused by fright or intense grief—has turned gray or white in a short space of time. In a certain class of novels one frequently sees it stated that some one's hair turned white in a single night, and such a remark is usually received with skeptical incredulity by the ordinary well-educated reader.

However, an occurrence of this nature is not impossible, although it must be said that it is in a high degree improbable. Perhaps there have been few, if any, instances, in which an individual's hair has turned absolutely white in twelve hours, but there is no reason why the human hair should not become blanched or gray in a comparatively short period of time.

An editorial in a recent number of the London *Polyclinic* treats of the subject and says: "There is nothing in the doctrine which involves the element of physiological impossibility; on the contrary, there are certain facts which go to show that it may quite well be true. In the first place, it has to be remembered that a gray hair is not necessarily one that has lost its pigment. The essential change appears to be some alteration in the nutrition of the hair leading to the formation of minute bubbles of air in the substance of the shaft." A gradual atrophy of the pigment cells does no doubt occur in old age. But even here it would seem that the real fact which causes the hair to lose its color phenomenon is the appearance of air globules in its tissue.

The change in the hair structure which leads to grayness is without doubt produced by some alteration in the nervous control of the hair tissue. The suddenness of the change, which in certain instances is not in dispute, must be taken to exclude the possibility that it is caused through the agency of the blood-vessels, and by a consequent modification of the nutritive supply. It must be due to an influence acting directly through the nervous system.

Dr. Robert Jones of the London County Asylum, referring to the sudden whitening of the hair of a patient under his charge, writes as follows: "May not such cases of sudden blanching through intense emotion be analogous to the change which is known to occur naturally in the lower animals, and thus be one of those reversions which we still meet with in the physical and mental deterioration of human beings, also indicating that a sudden influence through the nervous system is brought to bear upon the organism, necessitating sudden transformation if this organism is to continue its existence under its new environment.

It would seem, then, to have been demonstrated in a fairly conclusive manner that there is no inherent impossibility in a person's hair, through the influence of violent emotion, to blanch suddenly, and that the cause of this change of color is not due to the cutting off of the blood supply and consequent lack of nutrition, but is owing to some alteration in the nervous control of the hair tissue.

Report of Leprosy in the United States.

The report of a commission of surgeons of the Marine Hospital Service, appointed to investigate the origin and prevalence of leprosy in the United States, has recently been transmitted to Congress. The report shows 278 cases of leprosy in the United States, distributed by States as follows: Alabama, 1; California, 24; Florida, 24; Georgia, 1; Illinois, 5; Iowa, 1; Louisiana, 155; Maryland, 1; Massachusetts, 2; Minnesota, 20; Mississippi, 5; Missouri, 5; Montana, 1; Nevada, 1; New York, 7; North Dakota, 16; Oregon, 1; Pennsylvania, 1; South Dakota, 1; Texas, 3; Wisconsin, 3.

Of the total number 176 are males and 102 are females; 145 American-born, 120 foreign-born, and the remainder of undetermined nativity. It was stated to the commission that 186 of the cases were contracted in the United States, but the opinion is expressed by the commission that this number is too large, and that some of these cases were brought from abroad.

Summarizing, the commission states that the number of cases of leprosy in this country is smaller than is generally believed. It also states that the disease is transmitted from one person to another within the United States, such conveyance being most noticeable in the States on the Gulf Coast. It is reported that a large number of the cases are at large; that at present only seventy-two cases are provided for by the States or cities in which they are resident, and that many of the cases now at large, if not all, would be willing to be cared for by the public if proper isolation hospitals existed for their treatment and comfort. The commission recommends the establishment of a retreat for lepers, and express the opinion that it should be in the arid belt of the Southwest, or in the similar region further north, or on an island in the Gulf of Mexico, or on the Pacific coast. Of the 155 cases reported from Louisiana 101 are in Orleans County and 37 are in the leper home at Iberville. Of the 7 cases in New York 4 are in Kings County and 3 are in New York City. The commission expresses the opinion that the figures given do not represent the total number of lepers in the country, because the loathsome character of the disease causes persons so affected to conceal the fact as long as possible. The report states the belief of the commission that the disease is most frequently contracted through the inhalation of dust from places inhabited by lepers.

Does Ability Depend upon Physique.

In the *Practitioner* of March is an article by Mr. James Cantlie, M.B., F.R.C.S., on the health of the people. Mr. Cantlie wrote on the same subject some years ago, and uttered a warning with regard to the degeneration that is taking place among dwellers in large cities, and especially among Londoners.

In the course of the article the writer considers the question as to whether ability depends upon physique. He commences by defining ability as he conceives it, which differs but little, if at all, from the ordinary conception of the term, and then says it frequently occurs that our greatest thinkers and our foremost men in many branches of life are far from robust. Pale, sunken-cheeked men, with an insignificant frame and a troublesome digestion, are often endowed with a mental capacity of the highest order. With these men in view, it is often argued that it is brains that are wanted nowadays, not muscle; we are apt to console ourselves that what the town-reared child loses in physique he or she gains in the rapid development of his or her mental power.

The typical citizen of the United States is pictured as a tall, gaunt, dyspeptic-visaged man with hollow cheeks and lined features, and we are told to look upon him as the concentration of progressive ability. Can this be? Can man's frame and physique be changed, and yet what we call a healthy race continue? Are the men just cited the kind of human beings wanted for the future, and if so, is this a healthy individual, and are his children to inherit the earth.

Mr. Cantlie replies to his own question by saying that, "We will let the United States answer for themselves—but as to Great Britain, such men are not the type we hope to see become general."

In the first place it may be said that the evil effects upon the health and physique of living in large cities are as greatly deplored—though not so evident—in this country as in Great Britain, and that the matter has for long received the weighty consideration of thinking men, with a view to bettering the condition of things. It is quite true that town dwellers deteriorate physically, but it is by no means certain that they, as a rule, excel in mental powers. But even if it be so, this superior agility of brain will not compensate for the loss of stamina and virility which is almost invariably the lot of a descendant of dwellers in cities.

Regarding Mr. Cantlie's remarks on the European's idea of a typical American, although the picture is not entirely out of drawing, yet it is sufficiently so to convey a mistaken impression of the inhabitants of America taken *en masse*. The American whose ancestors have been in the country for generations or perhaps centuries to be a [illegible] [illegible], progressive, and powerful, though its individual [illegible] [illegible] and possibly unhealthy and some [illegible] and [illegible].

But the fact must always be borne in mind that the United States is constantly taking in fresh blood, which keeps up the standard of the population as a whole, to a height quite equal, if not superior, to that of any European nation.

No one, however, can disagree with Mr. Cantlie's contention that vitality without physique is not of much use, and one that [illegible] to degenerate the physical [illegible].

Loss of Life in the United States by Lightning.

Mr. Alfred J. Henry, Professor of Meteorology at the Weather Bureau, U. S. Department of Agriculture, has published a bulletin relating to the above subject.

Statistics of the loss of life by lightning have been collected for a period of eleven years, but for the earlier part of that time the results of the inquiry were so incomplete as to be worth little as a means of accurate information.

The number of persons killed by lightning during 1900 was 713; of this number 291 persons were killed in the open, 158 in houses, fifty-seven under trees, and fifty-six in barns. The circumstances attending the deaths of the remaining 151 are not known. Nine hundred and seventy-three persons were more or less injured by lightning during the year.

In a previous paper on this subject, the writer had occasion to discuss the relative frequency of fatalities by lightning in the several States and Territories. At that time, since the statistics covered but three years, it was thought inexpedient to draw conclusions from them. The addition to the previous record of the complete data for the years 1899 and 1900 makes it possible to form some idea of the death rate due to lightning in the various States and Territories. It is obvious, remarks Professor Henry, that the number of fatalities must depend partly upon the frequency of lightning strokes per unit area, partly upon the density of population, and partly upon the character of the thunderstorms which traverse the region. In the United States thunderstorms occur with considerable frequency over all the territory east of the 100th meridian, save a narrow strip along the northern border. West of the above-named meridian, except in the Rocky Mountain region, the frequency steadily diminishes, reaching practically zero along the immediate Pacific Coast. There are three regions of maximum thunderstorm frequency, viz., one in the southeast, with its crest over Florida, one in the middle Mississippi valley, and one in the middle Missouri valley. The average number of days with thunderstorms annually in the first named region is forty-five, in the second thirty-five, and in the last thirty.

The greatest number of fatal cases occurred in the Middle Atlantic States, and the next greatest in the Ohio Valley and Tennessee, with the Middle and Upper Mississippi Valley a close third. The greatest number of deaths in any single State during the five years, 1896-1900, occurred in Pennsylvania—186—followed by Ohio, with 135, and Indiana, Illinois, and New York with 124 each. The greatest fatality from a single stroke occurred at Chicago, Ill., where eleven persons, huddled together in a zinc-lined shanty, met instant death by a single bolt.

Professor Henry points out that there is not in the different parts of the country that accordance between the number of lives lost by lightning stroke and the number of thunderstorms which might be expected. The low percentage of deaths in the Gulf States and Florida, where the average number of thunderstorms is higher than elsewhere, may possibly be ascribed to two causes: First, the smallness of the population, and, second, the less violent character of the thunderstorms which prevail in that region.

The nature and classification of thunderstorms, as well as advice with regard to conduct during their progress, are entered into.

The following rules are laid down with regard to an individual struck by lightning: (1) Make the subject breathe by artificially imitating the respiratory movements of the chest; (2) Keep body warm; (3) Send for a physician, and, in conclusion, it is noted that lightning frequently causes a temporary paralysis of the respiration and heart beat which, if left alone, will deepen into death, but if intelligently treated will generally result in recovery.

Malaria Infection.

In the February issue of the *Bulletin* of the Johns Hopkins Hospital is a paper by Leonard K. Hirshberg and Gustavus C. Dohme giving the result of investigations made by them with regard to the distribution of the malaria-bearing mosquito in the neighborhood of Baltimore.

The conclusions at which these investigators arrived with respect to the extirpation of mosquitoes do not altogether agree with those of others who have made a study of the matter.

They do not believe it possible to exterminate mosquitoes by means of oil, and declare that the only antidote against contracting malaria is the mosquito net.

They are also of the opinion that malaria should be included among the infectious diseases and that cases of malarial infection should be reported to the boards of health just as are contagious diseases, and thus enable precautions against the spread of malaria to be carried out under the proper supervision.

In concluding their paper these investigators say: "Of special importance is the careful screening of doors and windows by wire gauze or mosquito netting, as suggested by Celli. Where this cannot be done, fitting the beds with netting will offer security, inasmuch as most anopheles bite at night. Again, persons already infected should be protected by screens to prevent infection of healthy mosquitoes and thus spread the disease broadcast, inasmuch as a patient having been infected in one place may carry it to another and infect the mosquitoes there."

The extirpation of mosquitoes, or even their abolition from the vicinity of towns, will be a much harder task than many have thought—that is, with the means now at disposal. The only safeguard against infection by the agency of mosquitoes is to carefully protect oneself against being bitten.

Sewage Disposal.

The Manchester Rivers Department has recently issued its report, which is an exhaustive and complete account of the latest methods of sewage disposal.

Manchester has made a well-earned reputation for her successful and careful experiments in this matter.

With regard to bacterial treatment of sewage, the report says: (1) The Roscoe beds (composed mainly of coke and cinders) were chiefly used for tank effluent from lime and copperas treatment, but do not, as a rule, yield such a pure effluent as septic tanks and bacteria beds, and the cost is increased as compared with the last named, by reason of the chemicals used; (2) Storm water-beds may be cheaply and effectively constructed of well-burnt and sharp clinkers; (3) The open septic tank was on one occasion relieved of some of its accumulated sludge, and although the smell of this was not disagreeable, the gases evolved caused sleepiness, with, in some cases, nausea, showing the necessity for ensuring thorough ventilation of septic tanks and connected conduits at such times. Roughly, about 50 to 60 per cent. of the sludge was destroyed by bacterial action. Such a tank, it is advised, should be worked lightly at first. Its beneficial results are not confined to the destruction of a certain percentage of sludge, but it also produced an effluent of more equable composition for further treatment, and one capable of ready nitrification. The utilization of the gas evolved from it is of questionable advisability. After speaking of the success and economy of the subsequent treatment of the open septic tank, the report damns with faint praise continuous filtration.

News of the Week.

The New York Academy of Medicine.—A stated meeting will be held in Hosack Hall, Thursday evening, April 17, at eight o'clock. The following papers will be read: "The Symptoms and Course of Smallpox," by S. Dana Hubbard, M.D.; "The Diagnostic Feature of this Disease," by S. Pollitzer, M.D.; "Its Treatment" (with lantern-slide exhibition), by George H. Fox, M.D.; discussion by Drs. Blauvelt, Dillingham, Huddleston, and others.

The Canadian Association for the Prevention of Tuberculosis will hold its annual convention at Ottawa on Thursday, April 17, and Friday, April 18, 1902.

College of Physicians and Surgeons, Columbia University, N. Y.—Plan for Raising the Standard of Admission.—The forthcoming announcement of the College of Physicians and Surgeons, the medical department of Columbia University, will contain a detailed statement concerning the plan for raising the standard of admission, upon which the President and Faculty have been at work for some months past. This plan has received the assent of the trustees, and will go into operation at once.

Heretofore, admission to the first year class of the College of Physicians and Surgeons has been open to any student who complied with the minimum requirements for a medical student's certificate, as those requirements are defined by the laws of the State of New York. A medical student's certificate is issued by the Regents to any applicant who presents what are known as forty-eight academic counts, these forty-eight counts being chosen from any subjects of secondary school study. The law provides, moreover, that a student who has obtained thirty-six of these counts may enter upon the study of medicine having one year in which to make good the twelve remaining counts. A student entering with more than thirty-six but less than forty-eight counts, has been known as a conditioned student.

The first part of the new plan at the College of Physicians and Surgeons provides that on and after July 1, 1902, no conditioned students whatever will be admitted to the first-year class. That is to say, the students who present themselves for admission in September next must have completed by that time the entire forty-eight counts required by law for a medical student's certificate.

A much more radical change is announced to go into effect on July 1, 1903, which will apply to the classes entering in September, 1903, and thereafter. By the terms of this part of the plan, no student will be admitted to the College of Physicians and Surgeons who has not obtained a medical student's certificate in one of two ways:

(1) By having successfully completed at least one full year's course in a college or scientific school in the United States, or having pursued an equivalent course of study at some European institution, the question of the equivalence being determined by the Regents of the University of the State of New York;

(2) By passing an entrance examination, conducted in June of any year by the College Entrance Examination Board, or in September of any year by the Committee on Entrance Examinations of Columbia University, or in part by both of these, provided only that if a portion of the examination is taken in June of any year the entire examination must be completed not later than September of the year following.

In accordance with the plan prevailing at Columbia University, the candidate for admission to the Medical School must offer fifteen points. Of this number, ten points are prescribed as follows:

English	3
Elementary Mathematics	3
Elementary Latin	2
And either Elementary French or German	2

The remaining five points that are required may be chosen from any one of the following subjects:

Botany, Chemistry, Drawing, Elementary French (if not offered among the ten points required), Intermediate French, Advanced French, Elementary German (if not offered among the ten points required), Intermediate German, Advanced German, Elementary Greek, Advanced Greek, Elementary History, Advanced History, Advanced Latin, Advanced Mathematics, Elementary Physics, Advanced Physics, Physiography, Spanish, Zoology.

Candidates who receive a grade of *C*=Fair=60 to 75 per cent. in subjects amounting to not less than twelve of the fifteen points offered, will be admitted to the College of Physicians and Surgeons conditionally, but in every such case the conditions imposed at entrance must be removed before the student is admitted to the second year of the course.

In order to offer an inducement to candidates to present themselves for examination upon Physics and Chemistry, or either of them, it is provided that those who receive a grade of at least *B*=Good=75 to 90 per cent. in either Physics or Chemistry, or both, may be admitted to more advanced instruction in the subject or subjects in which such grade is obtained as a substitute for the required Physics or Chemistry during the first year of the college course.

While it is the expectation of the President and Faculty that these new entrance requirements will materially reduce the number of students of medicine at Columbia, it is confidently believed that the higher standards will result in attracting the very best class of medical students to Columbia, and will pave the way for raising the standard of admission still more in the near future.

Medical Society of the State of California.—The thirty-second annual session of the Medical Society of the State of California will be held in Golden [illegible] Hall, [illegible] Sutter Street, San Francisco, on April [illegible], 16 and 17.

The Late Professor Paul F. Mundé.—The Medical Board of the New York Skin and Cancer Hospital, at a meeting held March [illegible], adopted the following resolutions:

Whereas, Dr. Paul F. Mundé, a member of the consulting Board of our hospital, has been removed from us by death, be it

Resolved, That in the death of Dr. Mundé the Board has lost one of its most eminent members, one whose professional attainments had given him a high reputation both at home and abroad, and whose noble character and conscientious life work had endeared him to his associates and friends.

Resolved, That our deepest sympathy is extended to his family in their great sorrow, and that a copy of these resolutions be sent to the medical journals for publication.

J. E. Janvrin, M.D. } Committee
L. Duncan Bulkley, M.D. }

An Opening for Internes in the State Hospitals.—Students about to graduate who are unable to secure positions in general hospitals, or young physicians whose terms are about to expire in general hospitals and who wish to enlarge their experience, are now offered an opportunity to enter the New York State hospitals as internes or clinical assistants. These positions provide lodging and board. Appointments are made for a year. Some twenty-eight positions will be opened in the fourteen State hospitals situated in the following places in New York State:

Utica, Ward's Island, N. Y. City (two hospitals), Buffalo, Gowanda (homeopathic), Rochester, Binghamton, Ogdensburg, Kings Park, L. I., Poughkeepsie, Flatbush, Brooklyn, Willard, Central Islip, L. I., Middletown (homeopathic). Although these are hospitals for the insane, yet they are so large that opportunities for experience in general medicine are abundant. Each hospital is well equipped with a pathological laboratory and apparatus, operating rooms, trained nurses, hydrotherapeutic and electrical devices, and good medical libraries. The field for study in general medicine is excellent, and surgical operations of all kinds are frequently performed either by resident or consulting surgeons. It is thought that many students who wish hospital experience and are unable to obtain it because of the relatively few places available in general hospitals will be glad to learn that positions of this kind have been thrown open to them. It is believed that young physicians wishing hospital experience will profit by a year's residence in one of these hospitals, and such as desire to continue in special work would be eligible for appointments subsequently to salaried positions in the State service.

No examinations will be necessary, but application must be made in person, with good references, directly to the medical superintendent of any of the above-named hospitals, or to Dr. Frederick Peterson, President of the Commission in Lunacy, 4 West [illegible] Street, New York City.

Army Medical School.—Twenty-three young medical officers were graduated at the recent closing exercises of the Army Medical School in Washington, the entire class having attained the general average of 80 per cent. necessary for graduation. The "honor graduates," who attained an average of 90 per cent. or higher, were Assistant Surgeons James M. Phalen, Conrad E. Koerper, Roderic P. O'Connor and Robert U. Patterson. Dr. Phalen was awarded the Hoff gold medal for having attained the highest average during the course. A large and distinguished audience was present at the closing exercises, including many of the notable men of Washington and neighboring cities.

The diplomas were presented by the Secretary of War after a short but excellent speech, in which he said that he regarded the highest privilege in life as being able to serve humanity, and the next highest privilege as being able to serve one's country. Few were fortunate enough to have the opportunity afforded the graduating class, he said, of at the same time serving both humanity and country. He paid a high compliment to the recent sanitary achievements of the Medical Department of the Army, and warned the members of the graduating class that only by earnest endeavor could they hope to maintain present standards.

Surgeon-General Sternberg's address, which, in view of his approaching retirement, was in the nature of a valedictory, was a summing up of what the Medical Department of the Army had accomplished since his entrance into the service forty-one years ago, and the great advance in medical science during that period. He stated that even as late as 1881, when he went to Johns Hopkins University to study bacteriology, there was not a bacteriological laboratory in the entire United States. Now every post hospital in the army had its bacteriological and chemical laboratory. He concluded with some excellent advice to the graduating class as to the purposes of the Army Medical Corps and the manner in which they, as members, were expected to comport themselves.

The exercises were concluded by an address by Lieutenant-General Miles, in which he welcomed the young medical officers into the military service. The Medical Department was the most popular branch of the military service, he said. In time of peace the society of its members was prized for their good-fellowship, education and gentlemanly conduct; in war they were looked to as the men through whom disease could alone be fought, and who shared in the dangers of battle to care for the helpless and assuage suffering.

Congress of the German Chirurgical Association.—The thirty-first congress of this association was held at Berlin on April 3. The discussion opened with the first treatment of wounded in battle as a subject. Professor Von Bruns, referring to the practice resulting from experiences in Cuba and South Africa, declared that antiseptic bandages were undoubtedly ideal for the battlefield.

Professor Trendelenburg introduced several patients, to illustrate the good effects of not probing or otherwise molesting wounds. He exhibited a remarkable case of a man who had attempted to commit suicide with a small caliber gun. The bullet penetrated the heart, but the wound healed quickly. Subsequently x-rays revealed the bullet lying in the right ventricle, moving with each beat. Eventually it became encased, and now moves ryhthmically with the heart, causing no inconvenience.

Cholera in the Philippines.—Cholera is slightly on the increase in and about Manila. Up to the present time there have been one hundred and eighteen cases and ninety-three deaths. Many of the deaths have occurred on ships in the harbor.

The natives and the Chinese are said to be panic-stricken, and, ignorant of sanitary and medical measures taken to stamp out the disease, evade vigorous quarantine restrictions of the Board of Health and escape into the country.

General Chaffee, in response to the request of Acting-Governor Wright, has detailed a number of army surgeons to supervise the provincial boards of health, and to regulate sanitary affairs. Detention camps will also be established for cholera patients and suspects.

Bill to Abolish Slavery in the Philippines.—Representative Patterson of Tennessee has introduced a bill to abolish slavery and involuntary servitude in the Philippine archipelago. The bill sets aside the treaty or agreement between General J. C. Bates and the Sultans of Sulu and Jolo, and prohibits the sale, purchase or gift of slaves in the archipelago.

Milk Bottles to Be Used for Milk Only.—The New York Health Board have just passed a resolution requiring milk inspectors to insist that milk bottles and cans be used for nothing but milk. An ordinance will shortly be introduced making it a misdemeanor for any person, milk dealer, retailer, grocer or housekeeper to use the bottles or cans for anything but milk.

Smallpox in Saranac.—Smallpox is reported to be present on a large scale in Saranac. The State Board of Health has been recently informed that the town of Saranac has one hundred and fifty cases of smallpox. This state of affairs was not reported until the last Friday in March. It is said that the health officer of the town reported that he had one hundred and fifty cases of a peculiar disease which was called Cuban itch in his country, but which, on investigation, turned out to be smallpox.

Anatomical Science in District of Columbia.—A resolution for the withdrawal from the President of a bill for the promotion of anatomical science in the District of Columbia has been introduced in the Senate. This action was taken in response to a letter from the Secretary of the Navy, who stated that the President had requested that the bill be withdrawn and amended so that its benefits might be extended to include the medical department of the Navy. There is no objection to the bill, but it is desired that the Navy as well as the Army—the beneficiary under the present bill—shall share in the advantages to be derived by securing subjects for anatomical study under this bill. The laws have been such in the past that sufficient cadavers for proper medical education in the District of Columbia have been secured only with much difficulty.

Plague and Cholera in India.—In Calcutta, during the period from December 22 to December 28, twenty-eight persons died of cholera, and during the same period there occurred twenty-eight plague cases and twenty-eight deaths.—*Public Health Reports.*

Cholera in Manila.—Recent reports from the Philippines state that the strenuous efforts of the Board of Health of Manila are having a marked effect in preventing the spread of cholera. So far the disease has been confined to the Filipinos and Chinese, and no cases have occurred in whites. The work of controlling and stamping out of the disease has been seriously interfered with by the scattering of the floating population of the part of the city in which the disease first appeared into other parts of Manila, and into the outlying districts. An unexpected obstacle has also appeared in the attitude of the friars, who are telling the Filipinos that the disease is not cholera, and that the Americans are taking the present sanitary precautions purely for the purpose of annoying the natives. This has provoked ill-feeling on the part of the Filipinos and excited an opposition to the execution of the sanitary regulations issued by the Board of Health. The latter has made a vigorous protest to the Archbishop of Manila, with regard to the attitude of the friars. One of the greatest difficulties in the way of carrying out sanitary reforms in the Philippines is found in the ignorance and superstition of the natives, their hostility to everything American, and their opposition to any change in the conditions of life to which they have been accustomed.

Sanitary Regulations in Yokohama, Japan.—The Sanitary supervision is vested in the Police Department of the Province of Keu. The city is divided into numerous precincts, in charge of a police officer and sanitary inspector. Daily reports are made to these concerning the sanitary condition of the precincts as well as the number of sick or dead. These are scrutinized, and if there is anything found of a suspicious nature, investigation is made immediately; in this way a perfect control is maintained over the entire city, particularly over the native population. The supervision over the foreign part is rather perfunctory, yet it is sufficient to guard against any serious infractions of the laws relating to the public health. It is remarkable how perfect the organization of the Police Department is and how well the native population is controlled.

Smallpox in Italy.—It is reported, February 17, that there were at Baselice, province of Benevento, 176 cases of smallpox in a population of 4,000 inhabitants. There is a large emigration from this province to the United States. All precautions, such as vaccination, careful physical examination, and disinfection of all effects, are being rigidly enforced.—*Public Health Reports.*

College of Physicians of Philadelphia.—At a stated meeting, held April 2, Dr. Wm. Osler read "A Memoir of the Late Dr. Alfred Stille." Dr. Frederick A. Packard read a paper entitled "On a Possible Cause of Intestinal Obstruction, with Remarks on the Use of Eserin in Atony of the Bowel." He related a case of new growth of the bowel, attended with frequent loose movements of the bowels and great abdominal distention, which it was thought was due to the formation of a loop in the bowel, in which fluid and solid matter collected, and acted like a plumber's trap, preventing the movement of intestinal contents until one or both arms of the loop were emptied. In this case, as in others, temporary relief was afforded by the hypodermic injection of eserin salicylate in doses of gr. 1-150. Dr. George Erety Shoemaker read a paper entitled "A Case of Typhoid Fever; Perforation and Operation." The patient was a girl, seventeen years old, in whom perforation of the bowel took place in the third week of a grave attack of typhoid fever. The abdomen was opened with little delay, the perforation sutured, and there was no further complication in this connection. The patient died, however, six days after the operation, apparently from the gravity of the primary disease. Drs. Chas. W. Burr and Wm. J. Taylor read a paper entitled "A Case of Jacksonian Epilepsy Caused by Tumor of the Brain Relieved by Operation; Hemiplegia and Muscular Atrophy; Death in Ten Months." The patient was an intelligent, well-educated man, about twenty-five years old, with a pronounced neurotic and psychotic family history, but with no distinctive personal history. For some six years he had, from time to time, been having attacks of focal epilepsy without headache and ocular symptoms. Finally, however, headache set in, together with choked discs, and then a diagnosis of tumor of the brain was made. Operation was undertaken and a portion of the motor cortex, supposed to be neoplastic, was removed. The patient was subsequently paralyzed on the opposite side of the body, and one convulsion followed the operation. He lived for ten months, but after death no autopsy could be [illegible] The [illegible] expressed that a sub- [illegible] growth was present. The [illegible] of the [illegible] to [illegible] the [illegible] destruction.

Crusade Against Cancer in Germany.—The crusade against cancer is being actively pushed in Germany. The Government is about to establish two institutes for its treatment in Berlin, [illegible] and $75,000 [illegible] has been [illegible] to [illegible] to be carried out under the direction of Professor [illegible] of Frankfort-on-the-Main Hospital.

A Light Institute for Vienna.—Under the protection of the Archduke Otto and the premier member of the Austrian House of Lords, Prince Max Egon Fürstenberg, a committee has been formed in Vienna for the foundation in that city of a special establishment for lupus cases on the lines of Finsen's Light Institute at Copenhagen. The estimated cost is $300,000. At the head of the list of contributors is the name of his Majesty the Emperor Francis Joseph, who gave 10,000 crowns from his privy purse.—*British Medical Journal.*

Attendance at McGill University, Montreal.—The total number of students attending classes at McGill University during the present session is put down at 1,113, divided among the different faculties as follows: Law, 61; medicine, 491; arts, 394; applied science, 151; and veterinary science, 16. In 1901 the total number of degrees conferred was distributed as follows: Law, 17; medicine, 93; arts, 42; applied science, 51; and veterinary science, 3.—*Lancet.*

International Medical Congresses.—The Second International Congress for Electricity in Medicine and Radiography will be held at Berne from September 1st to the 6th, 1902, and the Second International Congress for the Prophylaxis of Syphilis and of Venereal Diseases will be held at Brussels between the same dates.

Obituary Notes.—Dr. Delavan Bloodgood, Medical Director in the United States Navy, died of heart disease March 31, after an illness of several months, at his home, No. 320 Clermont avenue, Brooklyn. He was born in Erie county, New York, seventy-two years ago, and was graduated from Madison University and the Jefferson Medical College. His first commission in the Navy was in 1857 as Assistant Surgeon. He was made Past Assistant Surgeon in 1861, a Surgeon in 1862, a Medical Inspector in 1875, and a Medical Director in 1884.

After serving with squadrons in Indian, European and Pacific waters, he was assigned to home duty in 1870. When he was retired in 1893 he had charge of the naval laboratory.

Dr. William H. Clark, of Bellingham, Mass., was struck by a locomotive at a grade crossing on the 15th inst. and was instantly killed. Dr. Clark was graduated from the New York University Medical College in 1882. He engaged in general practice at Tolland, Conn., his native town, and later at Ipswich, Mass. He was Medical Examiner for each of these towns and secured a lucrative practice. He removed to Bellingham two years ago. He was a member of the Baptist denomination, prominent in church affairs, and a man of sterling integrity. His age was fifty-one years.

Dr. Patrick Thorburn Manson, eldest son of the well-known authority on tropical diseases, met with his death by an accident at Christmas Island shortly after his arrival there. Dr. Manson was a young man of great promise, and his untimely death is a loss to his country and to science.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

[illegible]

London, March [illegible]

The Midwives Bill has been pushed through the standing committee at last and has therefore a good chance of passing this year. Amendments of every kind were proposed by every [illegible] and the scheme [illegible] forward is likely to be [illegible]. It is a sad result of professional apathy [illegible] The [illegible] Midwives [illegible] The [illegible] who have [illegible] the [illegible] of a few [illegible] poor [illegible] and the [illegible] who have [illegible] these [illegible] experience.

The recent debate of the Chelsea Clinical Society was this year devoted to cancer and furnished an opportunity for a review of our additions to the knowledge of the subject during the last decade. Dr. James Galloway opened the debate with a reference to the last great stimulus to investigation on the subject, the [illegible] of the theory of the parasitic origin of the disease—a hypothesis which, he admitted, has been gradually weakened, with unfortunately a corresponding diminution in the activity of research. Little had been added in support of Cohnheim's theory that tumors were due to the abnormal and late development of embryonic tissue. Dr. Galloway found the accumulated evidence rather against this explanation. Epithelial cells transported into tissues of a different nature were capable of multiplication and of the formation of new epithelial masses, but this did not account for the new additional characteristic of malignancy when present. The dangerous attribute of the malignant tumor was not simply the power of multiplication possessed by its cells, but the fact that these cells invaded the neighboring tissues where normally they might not exist. Passing on to the parasitic hypothesis, Dr. Galloway said none of the structures described as parasites of protozoal nature had stood the test of criticism. Clinical experience gave but grudging support to the parasitic theory of cancer, but there was some evidence bearing upon it in prolonged morbid states sometimes preceding it for years, e.g., Xeroderma and abnormal pigmentation.

Dr. Tatham, superintendent of statistics of the registrar-general's office, gave some information from the statistical aspect. During the last four years the deaths from malignant disease averaged 25,000 a year. These diseases in the aggregate, i.e., without limitation as to the organs affected, were more fatal to women than to men, 875 per million as contrasted with 672. But the excess is caused by the tendency to attack the female reproductive organs. Subtracting the deaths from cancer of the ovaries, uterus and breast leaves a remainder death rate below that of males. Thus in the four years 1897-1900 the death rate, less that due to the generative organs, was 645 per million for males and 568 for females. In recent years the mortality had increased very rapidly in both sexes. Although at the present time women suffer more than men from cancer, the disease during the last thirty years had increased among men much more rapidly than among women.

Dr. Beatson said that by cancer he understood a morbid process where epithelium was placed in the body, resulting in a structure made up of epithelial cells which multiplied, invaded the surrounding tissues and travelled along the lymphatics. There was a link between malignant and benign tumors due to the common origin from epithelial cells. While differentiation masked the primitive epithelial form of all cells, it was not likely that the form was completely eradicated unless in the very highly specialized tissues. The less highly specialized might revert to the primitive form, and this explained the fact of benign tumors becoming malignant. If a tissue highly specialized were attacked by the influences causing tumor growth, the result would be limited—that is, a benign tumor. If a tissue were only slightly differentiated there would be great proliferation and indefinite growth—a malignant tumor. Malignancy and benignancy thus depended on the proliferating power of the cells, and that power on their degree of specialization. Having referred to the similarity of cancerous to embryonic tissues and the relation of malformations to neoplasms, Dr. Beatson passed to the question whether cancer was a local disease or the local expression of a general disease. He held that in the initial stage it was purely local, commencing in an alteration of the cells of the part affected. The factors starting the proliferation were either from within or from without. Of the latter only parasites were considered. To the parasitic hypothesis he made three fatal objections: (1) Congenital tumors, (2) Secondary growths, and (3) Absence of toxins. He believed in one intrinsic cause that explained the commencement of local cell proliferation and based that belief on the results of oophorectomy in mammary cancer. After oophorectomy there was a disappearance of cancerous tissue. Various inadequate explanations of this had been offered. He thought the explanation was to be found in facts connected with the testes and ovaries. Both prepared cells to perpetuate the species. He considered a secretion of some kind was elaborated by all the tissues in the body under the stimulus of these organs, and that constituted a fructifying fluid giving them their procreative power. Such a fluid was likely to influence cells of great proliferating power, and, therefore, tumor formation.

Sir Mitchell Banks insisted again on the great increase in the prevalence of cancer and restated his conviction that the increase in the consumption of food, especially the eating of such large quantities of meat, had something to do with the causation of cancer. Vast numbers of people eat meat now daily who fifty years ago only ate it once a week, while the wealthier eat it two and three times a day.

Mr. Pearce Gould followed with some interesting remarks. As to cure there was such a long procession of fatal cases that there is a tendency to regard cancer as absolutely incurable, but he was sure it was not so. They could not introduce a new force into the body and only hope to cure any disease by observing how nature dealt with it. Cancer did sometimes undergo spontaneous cure. It was, indeed, a very rare occurrence, but it did occur, and he related a very remarkable case.

Mr. Shield felt the futility of advancing theories of parasites, peculiar fluids, the action of one cell on another, and so on. Such hypotheses were easy to concoct but not easy to sustain. As to remedial measures, free and extensive operation was the best at their command—and best was often bad. He thought the mysteries of tumor growth were bound up in those of cell proliferation, as seen in the result of the contact of the sperm cell with the ovarian cell.

Dr. Blacker demonstrated the treatment of superficial cancers by Finsen's method, with the brush discharge and with *x*-rays. He showed the various apparatus used in these methods, and thought there was an extensive field of research in this direction.

The debate was then once more adjourned.

Thyrotomy was brought before the Medical Society by Mr. Shield, who thought the operation had a great future, not merely in malignant disease, but in other cases that could not be dealt with by the intra-laryngeal plan. He related some cases. One was for syphilitic stenosis and the result unfavorable. Others were for neoplasms, upon the nature of which the microscopists did not agree. One was for a large foreign body.

Mr. Hutchinson, Jr., was glad Mr Shield mentioned the failure of relief in the syphilitic case, for he had had just such a case, and would not operate in future. Malignant cases should be dealt with in the incipient, pre-cancerous stage.

Mr. Spencer said some cases of syphilitic stenosis could be operated on with advantage. He referred to the sudden supervention of difficult breathing in some patients.

Dr. St. Clair Thompson thought there was a future for thyrotomy, although the suitable cases were few It was not suitable for syphilitic stenosis. Tracheotomy was preferable in these cases, and after that there was often rapid improvement under iodide. He had not found the steam tent any use after thyrotomy. It was best to get patients into the sitting position.

Mr. Moullin read a paper on gastric ulcer at the Medical Society. He had asked Dr. Wall, medical registrar, to tabulate the cases at the London Hospital from 1895 to 1899. There were 246 cases, 202 women and 44 men. There were only four deaths among the women, and three of these were over thirty years old; the mortality among women under thirty being less than 1 per cent., while in those above thirty it was 6 per cent. In men, taking all ages, the mortality from hæmatemesis was 14 per cent.

Surgeon-General Sir Wm. Guyer Hunter, K.C.M.G., M.D., died on the 14th inst., aged seventy-one years. He served in the Burmese campaign, 1852–3, and subsequently in various parts. He was at one time Principal of Grant Medical College and Vice-Chancellor of the Bombay University. He was awarded the K.C.M.G., as a recognition of his great services in the cholera epidemic in Egypt in 1883. After retirement from the service he took an active part in public affairs; was a member of Parliament from 1885 to 1892, and in 1886–8 a member of the London School Board.

Another Surgeon-General, John R. Theobalds, late of the Indian service, died on the 7th inst., in his eightieth year. He retired in 1880, after thirty-two years of distinguished service.

The deaths are also announced of Surgeon-Major Turnbull, I.M.S., aged eighty-two years; Dr. John Preston, aged eighty-two; Dr. Frederick Hetley, J.P., D.L., aged eighty-one; Mr. Athol Johnstone, F.R.C.S., aged eighty-one. Patrick T. Manson, M.B., Lond., eldest son of Dr. Manson, F.R.S., only twenty-four years old, lost his life through a gun accident on the 11th inst.

OUR PARIS LETTER.

(From Our Special Correspondent.)

CHLOROFORM AND DISEASES OF THE HEART—NEW SANITARY LAW—PROFESSOR RICHELOT'S NEW BOOK ON GYNECOLOGY—IBSEN'S PLAYS ANALYZED BY DR. ROBERT GEYER—LIGATION OF AN ANEURISM OF THE AORTA BY TUFFIER.

PARIS, March 29, 1902.

AT a recent meeting of the Academy of Medicine, the use of chloroform to produce narcosis in cardiac patients was discussed at great length. Professor Huchard, the well-known heart specialist, said he considered that chloroform could be used in all forms of heart disease. The only counterindications would be cases of asystolia, dyspnœa due to alimentary toxæmia and the premonitory stage of pulmonary œdema. Fatty degeneration is generally considered a counterindication, but it is often mistaken for sclerosis. The patient should have been subjected at first to a treatment by digitalis and theobromin.

Pericardial symphisis would seem to be a distinct counterindication, but it is rarely recognized before an operation. Special operations offer more danger, such as anal dilatation. Chloroform should be given in small doses, so as to avoid laryngeal or toxic syncope. Dr. Huchard said that accidents were chiefly due to the manner in which chloroform was given, and were seen more frequently in the hospitals than in one's private practice. There was no special school for teaching chloroformization in France as there was in America.

Professor Berger said he gave chloroform without fear to cardiac patients, provided there were no symptoms of cachexia. In England, where there are special men for giving chloroform, they have as many accidents as in France.

Professor Le Dentu remarked that physiologists did not agree as to the cause of accidents. The physician should watch the condition of the respiration, the pulse and the pupils. The question is to know how far one can go with patients suffering from heart disease. Some consider that one should stop when the pupil ceases to react to light, others think that one can give chloroform until the pupil dilates. The first opinion would be the safer.

Dr. Lucas-Championnière did not consider ether as good as chloroform; he believed in giving small doses of chloroform. Bromide of ethyl was dangerous, according to his view.

Professor Richelot prefers to use chloroform, but uses a little bromide of ethyl at first.

The new sanitary law has at last been passed, and as it was published on the 15th of February it will be called the law of the 15th of February, 1902. This law has been more or less discussed during the last twenty years, and, according to Dr. de Lavarenne, it is still far from perfect. The mayors of the different towns are required, within a year, to prepare a sanitary regulation of measures to be taken in case of contagious diseases, and also to modify the hygienic conditions of dwelling houses. The Academy of Medicine is to prepare, within six months, a list of contagious diseases which are to be declared as such by physicians.

Professor Richelot, the well-known gynecologist, has just published a work on the surgery of the uterus, the vagina and the vulva ("Chirurgie de l'uterus, du vagin et de la vulve," Paris, 1902, Octave Doin, Editeur.) This work is not exclusively surgical in its tenets, as ideas of general pathology are found here and there. Dr. Richelot develops his theory of primitive utero-ovarian sclerosis, but he does not seem to have much confidence in the theory of an internal ovarian secretion.

An interesting thesis by Dr. Robert Geyer has just been presented to the Faculty of Medicine: It refers to the pathological psychology of the characters in Ibsen's plays. There would seem to be a great number of degenerates and insane in his works, and Dr. Geyer has shown the various forms of mental degeneracy, such as obsessions, hysteria, moral idiocy, maniac excitation, melancholia, neurasthenia, senile dementia. Ibsen has taken care to show the various causes which have brought about these forms of mental perversion.

Dr. Tuffier, the well-known surgeon, has operated proved to be a case of aneurism of the aorta. The patient was a woman forty years old, who had never had syphilis. She showed symptoms of an aneurism of the ascending portion of the aorta, and a thorough examination by means of auscultation, Röntgen rays, and sphygmography led Dr. Tuffier to consider that the sac communicated by a narrow opening with the aorta. Specific treatment had no effect upon the tumor, and as the tumor was increasing in size and causing discomfort, Dr. Tuffier operated at the patient's request. Dr. Tuffier was able to separate the aneurism and to ligate, but he made a grave error, as he admits, which was to leave it. Gangrene set in and hemorrhage took place. Death took place very rapidly. Dr. Tuffier's description of the operation, which he [illegible], and during which the patient died, is [illegible].

SEEDS IN THE APPENDIX.

To the Editor of the Medical Record.

SIR: Dr. Kennedy, in the MEDICAL RECORD for April 5, seems to doubt the presence of seeds in the vermiform appendix. In 1885 I made a post-mortem examination of a man who died after an illness of five days. Several experienced surgeons diagnosed the case as acute peritonitis. Around the vermiform appendix was a small abscess containing about two ounces of pus. In this pus was an apple or pear seed; in an opening into the vermiform appendix a second seed was found engaged, and a third seed was found in the cavity of the appendix, also a hardened fecal mass about one-fourth of an inch in diameter. All the seeds were similar. The openings through which the seeds escaped were as round and smooth as if cut with a hollow punch. The appendix was about three inches long.

Dr. Roberts at the time related a case in which he found a watermelon seed in the appendix which caused death. This was before the days of appendicitis. I have seen several operations for acute appendicitis, but have not found any more seeds nor seen the appendicitis sought. On one occasion an operator removed an apparently healthy appendix. JOHN W. KATES, M.D.

FRANKLINVILLE, N. Y., April [illegible], 1902.

ANTISEPTIC MIDWIFERY.

To the Editor of the Medical Record.

SIR: I have been much interested in the article by Dr. Valentine Browne which appeared in last week's issue of the RECORD under the heading "Unnecessary Antiseptic Treatment in Midwifery." Would it be presumptuous for a practitioner, a recent graduate, to point out a few—let us say—inconsistencies in the doctor's logic?

In the first place, the use of antiseptics in obstetrics is calculated to prevent rather than to cure puerperal sepsis. And what right had the doctor to hope that every case of labor would be rendered safe by the use of antiseptics? Did not the best writers tell us that these deplorable cases of puerperal sepsis will occur, carefully as we may guard against them? Was not the doctor a little too optimistic when he mounted his new hobby?

Now, let us suppose that a case has become septic. What are the conditions present in that woman's parturient canal? Is it not true that the uterus contains blood clots and bits of placenta? Is it a fair test of the new treatment to allow a nurse to flush out the vagina of such a case with carbolic acid, and then cry with a loud voice that the treatment is not efficacious?

In the doctor's second case the patient's temperature ranged from 102° to 105°. This lasted for six days, when the patient died. I was not aware that the [illegible] of the antiseptic [illegible] compelled us to keep up [illegible] for six days. [illegible] But, inasmuch as that woman's uterus evidently contained something which the [illegible] had been unable to remove, might it not have been well to complete the new treatment by a curettage? Is it fair to condemn a treatment as inadequate when it is only half used?

In the third case I [illegible] with a [illegible] that [illegible] was [illegible], [illegible] letter. But, says the doctor, it was a slow recovery. Very likely. The uterus for the first few days following labor is a cavity of no mean proportions. When this cavity contains bits of membrane and placenta swarming with bacteria of the most malignant varieties, it seems reasonable to suppose that in spite of the protecting wall of leucocytes in the walls of the uterus some of the toxic products of the growth of these bacteria must escape into the system. Else why the chills, the headache, the characteristic high temperature? With a systemic disturbance of this severity, who has dared to lead the doctor to hope for a rapid and uneventful recovery?

Next the doctor attacks the arrangement of the ideal lying-in chamber. Nor does he spare the weekly urine examination. These things, says the doctor, are not practicable in poor practice. Is it fair then to conclude that they are absurd? I think Dr. Browne will grant me that codeine and heroin are excellent drugs to allay certain forms of cough. But because they are expensive and the poor cannot afford them, are they any the less efficient in the cases in which it is possible to use them?

But the especial grievance of my friend seems to be the post-partum douche, which he scores unmercifully, forgetting in his zeal that it has been relegated to the past these ten years, in company with the posset cup and the vernal dose of sulphur and molasses.

Might I add, in conclusion, that with one or two sutures introduced with reasonable care as soon after labor as possible, it is almost impossible to keep a perineum from healing rapidly and completely.

WM. H. WIGLAM, M.D.

[illegible] FIFTH AVENUE.

Book Reviews.

A GUIDE TO THE MICROSCOPIC EXAMINATION OF THE EYE. By Professor R. GREEFF, Surgeon to the Ophthalmic Department of the Royal Charité Hospital, Berlin. Translated from the Second German Edition by HUGH WALKER, M.D., M.B., C.M., Assistant Surgeon and Pathologist to the Ophthalmic Department of the Glasgow Royal Infirmary. Philadelphia: P. Blakiston's Son & Co., 1902.

This little volume of 171 pages will be heartily welcomed by those who are anxious to become familiar with the technique of the microscopic examination of the eye. In Part I. a discussion of the equipment necessary for such work precedes a consideration of the methods (employed in the microscopical examination of tissues) that are of service in the examination of the tissues of the eye. Part II. is devoted to a description of the *special* tissues of the eye and the methods best adapted for their examination. The descriptions are brief, sufficiently explicit and up to date. The name of the author is a sufficient guarantee of the excellence of the work.

THE PRACTICAL MEDICINE SERIES OF YEAR BOOKS. GUSTAVUS P. HEAD, Editor. Vol. III. The Eye, Ear, Nose, and Throat. Chicago: The Year Book Publishers, 1901.

In the present volume the chapter on the eye is written by Casey A. Wood, that on the ear by Albert H. Andrews, and that on the nose and throat by T. Melville Hardie, all of Chicago. This book has what is so often lacking in works of this class, a *good* index, for which the reader will return to the authors most cordial thanks. The chapters represent a careful gleaning of the literature of the year 1901. Frequent references to the original sources of information are a valuable feature. Several illustrations are scattered through the work. This is a year book, not a text-book. The treatment of topics is therefore necessarily somewhat fragmentary, but it seems well to illustrate the present view-point along the special lines of work indicated by the title. We congratulate the authors, and unhesitatingly commend the results of their labors.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. XIX. Edited by RICHARD H. HARTE, M.D. Printed for the Association. Philadelphia: W. J. Dornan, 1901.

This volume is the usual annual collection of papers read and discussed at the meeting of the American Surgical Association. Many of the papers have appeared in journals, but collected in one volume they offer valuable information upon many surgical problems. The volume is very well arranged, and will repay perusal.

ON THE CURE OF THE MORPHIA HABIT WITHOUT SUFFERING (Physiological Demorphinization), with a Note on the Physiological Method of Relieving the Craving for Drink. By OSCAR JENNINGS, M.D. (Paris), M.R.C.S. (Eng.). Second Edition, Revised and Enlarged. Wm. Wood & Co., 1901.

This little book of 211 pages is written pleasantly and clearly. It can be put safely into the hands of the physicians called upon to cure morphia addiction and of the victims of the habit. There is much encouragement for the latter, for the writer bases his discussion and his methods largely upon his personal experiences, and the successful result in his own case. The "physiological" method is based upon the recognition of the fact that the "want of morphia makes itself felt chiefly in three directions. (1) A condition of restlessness, and sometimes of pain, depending upon the want of an artificial stimulus to the brain cells . . . ; (2) By failure of the heart's action and a sluggishness of the circulation . . . ; (3) An excessive secretion of acid in the stomach." The author wisely adds that it is not only necessary to meet these conditions, but also to isolate the patients so as to protect them against "the irresistible impulse that prompts even the best-intentioned to succumb to its fascination." Jennings advocates the gradual reduction of the drug, the substitution of rectal injection for the hypodermatic syringe; the use of digitalis (other heart stimulants would surely be in order), bicarbonate of soda, and the hot-air bath. "By remedying functional depression . . . the hot-air bath is chiefly useful." There is much else in this book that is well worth knowing.

MOSQUITO BRIGADES, AND HOW TO ORGANIZE THEM. By Major RONALD ROSS, Indian Medical Service. New York: Longmans, Green & Co., 1902.

DR. ROSS, who was the first to demonstrate the passage of the malarial parasite from the stomach of the infected mosquito into the salivary gland, and to whom medical science is indebted for the identification of the species of the malaria-bearing mosquito, has recently been in charge of an experimental campaign against mosquitos in the reduction of malaria in West Africa, and speaks with authority on the subject of which he writes. As its title indicates, the purpose of the book is to show the most modern and efficient methods of waging war against mosquitos. The first section of the book is devoted to an enumeration and consideration of various facts in the life history of mosquitos, a knowledge of which may be applied to their destruction. Popular misconceptions with reference to these insects are corrected, and the character of the breeding places of Culex and Anopheles is described. In the second section of the book advice is given with regard to the raising of funds to prosecute the work, the organization and distribution of work of the Culex and Anopheles "gangs," and the destruction of larvæ and adults. To the latter, however, he believes little attention need be paid if the breeding-places are properly attacked. Dr. Ross does not by any means regard the extermination of mosquitos from any given locality as practicable, but he does believe that such great reduction may be accomplished in the number of these insects as to practically stamp out locally the diseases which they transmit. The proof of the truth of this idea has recently been furnished by the elimination of yellow fever from Havana by measures directed solely against the mosquito. In an appendix, Dr. Ross gives a summary of the results of the warfare against mosquitos as carried on, among other places, on Staten Island and in Havana. A note of sarcasm against popular ignorance, indifference, and inertia runs through the several pages, and it is easy to see that the writer's patience has been sorely tried by the slowness with which British officialdom grasps and acts upon new ideas. The book is well written in a popular style, is free from unnecessary material and diffuse generalities, and furnishes, in compact form, much information of which the municipal health officer, army surgeon, and, in fact, every one living in a mosquito-infected district, should be possessed.

PROGRESSIVE MEDICINE. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia, etc., assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-Patient Department of the Jefferson Medical College Hospital. Vol. IV., December, 1901.

THE closing volume of the year of this quarterly digest goes over the advances, discoveries, and improvements in the realms of digestion, genito-urinary matters, surgery of the extremities, orthopedics, kidney diseases, physiology, anæsthetics, fractures, dislocations, hygiene, and closes with seventy-five pages of "Practical Therapeutic Referendum," by E. G. Thornton.

The volume is in keeping with the others of the year, and with those of other years. There is an excellent résumé of all that pertains to diabetic gangrene.

Among the other contributors are Einhorn, Belfield, Bloodgood, Bradford, Brubaker, and Baker.

THE BABY, HIS CARE AND TRAINING. By MARIANNA WHEELER. 12mo. New York and London: Harper & Brothers, 1902.

THIS is a model book of its kind, and is filled with sensible suggestions regarding the care of the infant in all minor matters pertaining to its health and comfort. The young mother who may take upon herself the responsibilities of the nurse will find in this small volume an abundance of useful hints to guide her in all the little emergencies which may arise in the discharge of her multitudinous functions. The author shows great discretion in the selection and treatment of her subjects, and gives abundant evidence of her large and varied experience with babies in general.

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 3, 1902.

Physiological Heart Murmurs Produced by the Electric-Light Bath.—Thomas Howell examined fifty-two persons with especial reference to the effects of the bath on the heart, and murmurs were heard in the heart or arteries, generally both, in nearly every case. In some instances these murmurs were both short and soft, while in others they were rough and long. As a rule, they were evanescent, but sometimes they persisted for twenty or thirty minutes, particularly in the vessels. Of these fifty-two persons only eight had organic heart disease, and only six had functional murmurs. Sansom holds that under nervous (vasomotor) disturbance the arteries may be unequally affected in their caliber, some lengths being contracted, others dilated or of normal size; so that the blood passes from narrower to wider channels. The author says that he has nothing additional to offer in explanation of the arterial murmurs produced by the electric-light bath.

Angina Cruris (Intermittent Claudication), and Allied Conditions, Including Painful Cramps, with Remarks on the Importance of Examining the Pedal Arteries.—G. L. Walton and W. E. Paul reach the following conclusions: (1) The occurrence of the paroxysmal pains of angina cruris with pulseless pedal arteries is too constant to be explained by coincidence; (2) The painful paroxysms are probably of vascular origin, and result from vascular spasm, coupled, perhaps, with increased blood pressure acting on vessels already partially occluded, whether from local or general disease, from senile changes, or from congenital tendency to angio-fibrosis; (3) Recurring painful cramps of constant seat probably represent a modified form of angina cruris; (4) It is important to examine the dorsalis pedis and posterior tibial, as well as the radial and temporal arteries, in all cases in which it is desirable to estimate the bearings of the vascular condition upon disease in the central nervous system or elsewhere.

Journal of the American Medical Association, April 5, 1902.

A Service View of Hernia.—E. F. Robinson gives his experience with hernia among the soldiers in the Philippines. He reaches the following conclusions: (1) Additional care should be exercised in the enlistment of men with absolutely sound abdominal walls, and they should not be over weight; (2) Regular exercise should be insisted upon with troops in the tropics, even during so-called "field service," that the general physique may remain above par. There is too great a tendency among officers and men in a tropical country to relax all form of physical exercise and to think, because they are in the field, such is not necessary; (3) The old abdominal cartridge belt should be replaced by some form of belt, if necessary, by which the weight is swung from the shoulders and the abdominal muscles are not restricted; (4) General attention should be given to hygiene, and the avoidance of the causes of disease in general is, of course, an important factor in preventing hernia; (5) Early operation is advised in all cases of inguinal and femoral hernia.

Hypnotics: Their Use and Abuse.—A. W. Rogers notes the necessity in this class of cases of natural measures and says that an occasional placebo is a helpful substitute. We are under the necessity of studying each individual case separately. One hypnotic will not be the best in every case. In paraldehyde we have a hypnotic speedy in its action, producing quite natural and refreshing sleep and accompanied by but few and slight after-effects. In fact, its only disadvantage lies in its disagreeable odor and taste, and the odor left on the breath. It will be taken quite readily when mixed with coffee, aromatic elixir, or made into an elixir according to the pharmacopeia. Trional is less prompt than paraldehyde, but produces a more prolonged sleep, is best given in hot milk after retiring. It is often of advantage to give small doses of sulphonal during the latter part of the day, and twelve grains of trional at bed-time. In doing this we usually secure for our patient six to eight hours' good sleep. Sulphonal is very slow in producing sleep and very prolonged in it effects. It is best given in five-grain doses, two hours apart, through the day, until twenty, and in exceptional cases thirty, grains have been taken. We can expect the patient to sleep that night and be drowsy the following day. In some cases depressing effects may be evident two and even four days after such dosage. Sulphonal is best used in cases of pronounced mental and motor excitement.

Philadelphia Medical Journal, April 5, 1902.

The Relation of the Tubercle Bacillus to Pseudoleukæmia (Sternberg's Disease).—Joseph Sailer believes that it is the prevailing opinion among pathologists at present that there are three forms of disease of the lymph glands that have given rise to the pathological characteristics of pseudoleukemia. These are lymphosarcomatosis, tuberculosis and a peculiar infectious process the cause of which has not yet been determined, but which is regarded by some as the only true form of Hodgkin's disease. It is no longer questioned that the glands in many instances contain tubercle bacilli, which are capable of infecting guinea-pigs. This last point has been proven. It has been shown that in many cases with the characteristic histological picture of lymphoma, tuberculous glands and the bacilli may be numerous and virulent. But it does not necessarily follow that they are the cause of the pseudoleukemia. They may exist as a secondary or as an associated infection. There is still work to be done on this subject before definite and positive conclusions can be reached.

The Treatment of Carcinomatous Growths by Rontgen Rays.—George G. Hopkins states that the use of this therapeutic agent in the treatment of inoperable cancer is marvelous. With proper care and judgment we have a safe and certain cure for a very large class of malignant diseases which have heretofore been considered incurable. The writer has been treating cases of inoperable uterine cancer with considerable success. In treating malignant disease of the internal parts, a hard tube should be used and it should be brought as close to the surface of the body as is consistent with safety. The use of the Röntgen ray is now a well-established method of cure for carcinoma of the female breast. It has proved most satisfactory in the treatment of recurrent carcinoma after amputation of the breast. Carcinoma of the stomach requires the greatest amount of care and judgment in its treatment. Malignant disease of the face, in its various forms, is amenable to this agent, the odor disappearing with great rapidity. In cancer of the tongue the results have been wonderful.

New York Medical Journal, April 5, 1902.

The Differential Diagnosis between Disease of the Gall-Bladder and Disease of the Vermiform Appendix; with a Report of Two Cases.—The cases are reported by J. C. Kennedy, the first being that of a woman of fifty-six years. Diagnosis was doubtful but pointed to appendicular abscess, abdominal pain was radiating, but most marked in the right iliac fossa, fever, constipation, vomiting, right iliac region hard and rigid. Section revealed an empyema of the gall-bladder, which contained an immense number of calculi. Recovery was without incident, except that a biliary fistula lasted several weeks before healing. The second case was that of a man aged twenty-four years, who had had several attacks of biliary colic. In the present attack there was intense abdominal pain, constipation, no jaundice, continuous vomiting, fever, pain and tenderness over the lower border of the right lobe of the liver where a well-defined swelling was noticeable. Diagnosis doubtful, possibly ileus or gall-stone. Section revealed an abdomen full of pus, due to inflammation starting in the appendix, in which was found a large enterolith. This patient also recovered. The author makes some remarks upon the differential diagnosis between the two conditions noted in the title.

Pulmonary Embolism after Operations on the Bladder and Prostate.—E. L. Keyes, Jr., says that embolism in general is divided into three classes, according as to whether death is instantaneous or delayed, or whether recovery ensues. In the present instance he makes no such distinction but gives a brief review of previously recorded cases of embolism after bladder and prostate operations and adds three personal cases. In the first case death resulted two weeks after suprapubic prostatectomy, probably from uremia and embolus; in the second case a perineal prostatectomy was done, and the patient died suddenly on the sixteenth day; in the third case after the suprapubic operation, death came suddenly on the evening of the second day. Keyes has been able to find but seven other cases recorded. In the entire ten but two came to autopsy, thus positively confirming the diagnosis. He says that, admitting that the pelvic veins by their large size, their sluggish circulation, and their absence of valves, are specially liable to thrombosis, no organ has the anatomical predisposition to thrombosis possessed by the prostate. Itself a vascular organ, it is placed at the bottom of the pelvis, surrounded and permeated by a plexus of large veins, whose circulation is so slow that they commonly contain phleboliths in later life. Any cutting, tearing, or burning of this organ must assuredly cause a certain amount of venous thrombosis with the associated inflammatory reaction, and when the sluggish state of the periprostatic circulation is considered, the wonder is not that thrombosis should be frequent, but that it should be rare. Add the shock of operation upon the vitality of an elder man, add the inevitable uræmia for the first few days after operation and the it would seem that embolism should not more frequently result. Perhaps, at least, perhaps many cases which have been attributed to uremia or sepsis belong here.

American Medicine, April 5, 1902.

A Contribution to the Etiology of Appendicitis.—Arthur J. Patek summarizes his paper as follows: (1) Because of its anatomic characteristics and relations, the appendix is an organ of lower vitality and less resistance than are other parts of the intestinal tract; (2) Micro-organisms are normally present in the intestine, and await but an opportune moment when, in the presence of irritating secretions, they may excite an inflammatory reaction; (3) While appendical inflammation may undoubtedly originate de novo, there is no question but that (4) In many cases the appendical inflammation is a secondary infection, the primary focus being in the intestine proper, the result of an acute indigestion or a catarrhal inflammation; (5) Prophylaxis is the price of health. It may be possible to do much toward the prevention of attacks of appendicitis by careful regulation of diet and intestinal habit in health, as well as securing good intestinal drainage and antisepsis in the various gastro-intestinal diseases.

The Surgical Uses of the Hairpin.—J. Torrance Rugh enumerates many uses of the ordinary sterilized hairpin in surgery. He has found about eleven varieties and he classifies their uses under three headings: (1) When used in the natural shape, (2) When straightened, (3) When bent or twisted into various shapes. Under the first class he mentions the following uses: (1) To hold the hair away from the shoulders or neck during an operation, (2) To pin on dressings or bandages, (3) To remove concretions or foreign bodies from any sinus, canal or openings, (4) As a dull curet, (5) As an esthesiometer, (6) To catheterize a female. This is easily done by inserting the rounded end through the urethra, (7) To run under a blood-vessel, when compression is to be made to arrest hemorrhage, (8) To close a wound, (9) As a calipers or compass. When straightened it may be used: (1) As a probe, (2) As an applicator, (3) To wire the bones together in resections or fractures, (4) To rupture the membranes in labor, (5) Heated to cauterize parts, (6) As a hairlip pin, (7) To sound a child for stone in the bladder, (8) As a hook to extract foreign bodies from canals and sinuses, (9) As a tenaculum. When bent or twisted, it may be used: (1) As a nasal speculum, (2) As a retractor, (3) As an aneurysmal needle, (4) In lieu of a tracheotomy tube, (5) As a drainage tube, (6) To approximate the edges of a wound.

Medical News, April 5, 1902.

The Pneumatic Proctoscope.—James P. Tuttle describes this instrument as having the following advantages: (1) It does not require any uncomfortable position of the patient for its employment; (2) The lamp is outside of the main tube and thus does not obstruct the view in any manner; (3) The descent of fæces into the tube does not obstruct the light nor require its removal. The plug can be taken out and the tube cleansed by the introduction of small cotton wads, held in long dressing forceps without any material delay in the examination; (4) The plug containing the eyepiece is easily and quickly adjusted through the ground joint.

Leucocytosis as a Point of Prognosis in Appendicitis.—H. M. Joy and F. T. Wright conclude that (1) The leucocyte count is a valuable aid to prognosis in appendicitis, (2) This is distinct from its diagnostic value, (3) A high stationary, or an increasing count indicates a morbid condition of increasing severity, which demands operation no matter what the clinical symptoms may be. (4) A low stationary or decreasing count indicates that the severity of the case is abating and that operation may be safely postponed. Cases in which a falling count is accompanied by unmistakable signs of a generally bad condition form the rare exception to this second principle, and in them there is no chance of error, (5) No arbitrary set of prognostic values to be assigned to various degrees of leucocytosis can be constructed, (6) The count indicates when operation should be performed for the best interests of the patient, (7) Study of the blood-count enables it to be determined whether the operation for appendicitis can be postponed with safety.

The Lancet, March 29, 1902.

The Comprehensive Study of Thoracic Phthisis.—In the first Lumleian lecture F. T. Roberts makes the following classification of the causes of this malady: (1) Definite infection from without; (2) Infection from within—Auto-infection; (3) Personal inherent predisposition; (4) Causes acting on general system—Acquired personal predisposition; (5) External conditions and environment; (6) Special causes; (7) Local causes, acting more or less directly on respiratory apparatus; (9) Local predisposing morbid conditions; (9) General or remote predisposing diseases. The paper is an elaboration of the general subject of etiology according to the foregoing list.

A Case of Inoperable Cancer: Favorable Result from Oophorectomy and Thyroid Feeding.—The patient of W. Edmunds was a woman of thirty-six years, with cancer of the left breast. The gland and axillary contents were removed in 1894. Fifteen months later recurrence was noted in the scar, which was excised. Several subsequent deposits were removed under cocaine. In 1899 the disease appeared in the right breast, but progressed very slowly. In March, 1901, the ovaries were removed and thyroid feeding began. Two months later it was noted that the right breast had become much smaller and the patient's general condition had greatly improved. She has continued to do well up to the present time.

A Case of Appendicitis in Which the Appendix Was Lodged in, and Adherent to, the Femoral Canal.—J. H. Galton reports the case occurring in a woman of thirty-two years. Operation revealed the following conditions: The head of the colon was found to be adherent to the anterior abdominal wall just below the incision. It was extremely difficult to find the appendix, which was firmly bound down by a strong meso-appendix adherent throughout its length to the posterior wall of the abdomen and dipping down for a quarter of an inch into the femoral canal, to which it was adherent. A strong and old adhesion also bound it to the ileum. The meso-appendix was pierced at an inch from the cæcum, and a ligature which was passed round the appendix at this part gave control over the process during the operation. The adhesions of the appendix to the posterior wall were soft and separable by the nail, but in the process of doing this the soft and swollen appendix was torn in the middle, and both ends were at once secured with forceps and ligatures of carbolized silk. The separation was then continued till the tip of the appendix had been enucleated from the femoral canal. The strong adhesion to the ileum was then ligatured and tied with silk, and the meso-appendix was divided into four parts, each of which was separately ligatured. A portion of peritoneum was then dissected back from the appendix above the temporary ligature and a permanent ligature applied half an inch from the cæcum; the whole appendix was then cut off, a drop of strong carbolic acid was applied to the mucous membranes, and the deflected peritoneum was drawn over and secured by two fine silk ligatures. Recovery was uneventful.

Notes on the Treatment of Furunculosis, Sycosis, and Acne by the Inoculation of a Staphylococcus Vaccine.—A. E. Wright details his experiments along the line suggested by the title. His paper is illustrated by elaborate tables, which must be consulted in the original by those interested. He says that if we consider the matter rightly we shall see that the process of bacterial inoculation as applied to a patient who is the subject of a bacterial invasion is, in reality, a process of temporarily taking away from his power of resistance with a view to his receiving back that power with interest. It is, in short, a process of trading upon the patient's balance of resistance. When exploiting the method it will, then, be wise to inform ourselves beforehand concerning the resisting power of the patient. It will be wise, also, before adventuring, to learn what we can about the demands which will be made upon the patient's resisting power by the inoculation of that definite quantity of the bacterial vaccine which we propose to employ. The general results are expressed in a very conservative tone, for the writer says that in each case treated after an interval of three or four days, during which there was an improvement, symptoms of a certain amount of relapse manifested themselves both in the condition of the local infection and in the results of blood examinations. Wright states that after several further staphylococcus inoculations, which had been varied in time and with respect to dose, in accordance with the results of the daily blood examinations, the patient's condition was still that of a chronic staphylococcus invasion, associated in places with a certain amount of scabbing and infiltration. There would thus appear to be a very definite limit to the defensive reaction of the organism, a limit which comes into consideration also in the case of other inoculations.

British Medical Journal, March 29, 1902.

Intravenous Injection of Normal Saline Solution in a Severe Case of Hæmatemesis; Recovery.—H. E. Bruce-Porter gives an account of a case under his care. The patient was a woman of forty, and had had several slight hemorrhages. When the writer was called he found her extremely weak and blanched. A teaspoonful of extract of hammamelis with a little water was given every four hours. Nutrient enemata were ordered. Two days later there was another hemorrhage, immediately after which twenty minims of turpentine in water were given. A quart of normal saline solution was injected into the arm. For the first few days a hypodermic of ¼ gr. morphine was given. In a few days hæmatogen was begun, and in about two months from the time of the first hemorrhage noted the patient was able to go to the seaside.

A Short Note on the Surgical Use of Subcutaneous Injections of Carbohydrates in Exhausting Diseases.—Arthur E. Barker calls attention to the great value of the use of saccharosed subcutaneous infusion in the preliminary treatment, the operation, and after-treatment of exhausted patients. He uses a concentrated solution, which is sealed up in glass capsules, which can be diluted to the proper strength in a moment with the corresponding amount of boiled water. Such capsules can be carried about for every serious operation. The writer has so far never observed any sugar in the urine from the use of this method. He mentions the effect in septic cases of the increased secretion of urine induced by the free use of saline injections. The toxins are excreted in greater abundance and in greater dilution, which certainly helps the kidneys.

Remarks on Cases of Lymphangiectasis with Enormous Overgrowth of Cutaneous and Subcutaneous Structures.—Walter Whitehead reports several cases of this nature, one of which was a woman, aged forty. Her right leg was four times the thickness of the left. The patient was put to bed for entire rest. After ten days systematic massage was begun. In two days elastic pressure was applied from the toes to the knee. A porous, elastic bandage was used. A week later compression of the femoral artery was carried out by means of Skey's tourniquet. This was very gradual at first, but was increased until the circulation was nearly arrested. The tubercles were rubbed down with pumice stone, and induration and discoloration of the skin disappeared. The writer adds that the *rationale* of treatment is based on the following laws: (1) The lymphatics in the leg are divided into a superficial and deep set; the lymphatics of the same set anastomose freely with each other, but the two sets communicate only in the glands. This anatomical separation has much to do both with the etiology and also with the treatment of lymphatic disease; (2) The activity of tissue absorption, as a rule, is in an inverse proportion to that of circulation. When the force of circulation is weakened, the process of absorption is energetic; the serum of the blood passes through the walls of the capillaries in a more or less rapid stream in accordance with the blood pressure, irrigating the connective tissue and collecting in its interstices, and being drawn off by the efferent lymph vessels, in which the pressure is practically *nil*.

Münchener medicinische Wochenschrift, March 11 and 18, 1902.

Bactericidal Power of Röntgen Rays.—H. Rieder reports a continuation of the experiments begun by him in 1898 relative to this subject. The bactericidal power of the Röntgen rays was tested against the cholera spirillum, the bacillus prodigiosus and the colon bacillus. The microorganisms were inoculated into gelatine or agar and exposed to the action of the rays in Petri dishes, the covers being removed. After twenty to thirty minutes' continuous exposure to the rays many of the bacteria were killed, and multiplication ceased in nearly all. In every series of experiments, however, a few of the individual bacteria were not affected. Experiments have shown that the bactericidal power of the rays is not due to the fluorescent light, heat, ozone or electricity. So far as is known the culture media is not altered by the rays or made unsuitable for the growth of bacteria. Gelatine is never liquefied. It is not, however, to be assumed on the basis of the above experiments that the Röntgen rays possess any bactericidal action upon bacteria when present in the animal body. The evidence from animal experimentation is against such a supposition. As a rule, animals inoculated with pathogenic bacteria and exposed to the rays die sooner than similarly inoculated animals which are not thus exposed. It is not to be denied that in the human subject certain infectious diseases, particularly those of the skin, may be successfully treated by the Röntgen rays, but it does not seem probable, at the present time, that such success is due to bactericidal action.

Cutaneous Angioma in the Diagnosis of Carcinoma.—Albert Reizenstein writes in opposition to Leser's view that numerous cutaneous angiomas occurring in persons in young and middle life are suggestive or diagnostic of the presence of carcinoma. Such angiomas are to be considered as degenerative processes of the skin, which are commonly observed in elderly people, but which are frequently present in young individuals in whom no carcinomatous process can be demonstrated. Reizenstein has observed twenty cases of undoubted carcinoma and six cases in which the diagnosis was uncer-

[illegible]

Purpura Hæmorrhagica in Genital Tuberculosis. [illegible] the breaking up of tubercular foci [illegible] In this case, however, [illegible] was performed without the development of other tubercular manifestations.

Complete Uterine Rupture; Removal of the Organ Through the Abdomen. J. A. [illegible], Jr., reports two cases of [illegible] with extrusion of the fetus into the peritoneal cavity which were successfully treated by abdominal extirpation. Three operative methods are available in the treatment of rupture of the pregnant uterus: (1) Suturing the rent; (2) Supra-vaginal amputation of the ruptured uterus; (3) Total extirpation. Complete ruptures can only be sutured by the means of abdominal incisions. In incomplete rupture the extra-peritoneal method of suturing can be employed. The vaginal method of suturing is only available in cervical ruptures. Suturing methods, as a rule, give poor results. Satisfactory union is rarely obtained and the danger of infection is considerable. They are only to be recommended in superficial tears of the cervix. Supra-vaginal amputation can be accomplished by the extra or intra-peritoneal route. The first method (Porro's) is always to be preferred, as it is the more simple in execution and the dangers of infection are decidedly less than when the intra-peritoneal method is employed. Total extirpation may be accomplished either through the abdomen or the vagina. Although the abdominal method has been employed hitherto in only a relatively small proportion of cases, it is certain that it is the one to be preferred. Rupture of the uterus presents itself for treatment under two clinical conditions. (1) Accompanied by immediate serious hemorrhage. If immediate operation under the circumstances is impossible, the uterus should be emptied in the ordinary manner, the rent as far as possible closed, and a compression bandage applied. Eventually, Porro's operation should be performed. If immediate operation is possible total abdominal or vaginal extirpation should be done, but the former method should be given preference. (2) Accompanied by slight or no hemorrhage. Here the uterus should be emptied in the ordinary manner and the wound drained by iodoform gauze. If subsequent hemorrhage occurs, total abdominal extirpation should be done if circumstances permit; if not, Porro's operation or total vaginal extirpation. It should, however, be remembered that [illegible] is followed by the best results.

Deutsche medicinische Wochenschrift, March 13, 1902.

Official Notification of Tuberculosis. C. Fraenkel is strongly in favor of the official registration of tuberculosis. [illegible] an essential link in the chain of defense against the spread of the disease. Disinfection and isolation are without material avail unless notification is compulsory. The advantages of official notification are [illegible] in the statistics of those countries in which [illegible] has recently been made compulsory, as the United States, Italy, Saxony, Prussia and Norway. A differentiation is desirable between those cases of tuberculosis which can give rise to contagion and those in which this is impossible. The latter, however, should be kept under observation, since they may at any time become sources of contamination to those with whom they come in contact.

Parasitic Origin of Carcinoma.—By the means of special technique Feinberg has been able to demonstrate, histologically, the presence of protozoa in carcinomatous tissue, and he regards them as causative factors in the production of the same. It is evident that the first step in the demonstration of the parasitic origin of carcinoma must be the demonstration of the parasites in carcinomatous tissue and their identification. Unless this has been successfully accomplished the [illegible] of carcinomatous [illegible]

[illegible]

As the result of his observations, Feinberg draws the following conclusions: (1) Parasites are present in carcinomatous tissue which are different in morphology and staining characteristics from all known tissue cells. (2) These parasites are causative factors in the production of carcinoma. (3) They are encysted and their original and vegetative form is different from that here described. (4) The demonstration of these parasites in doubtful cases establishes a diagnosis of carcinoma.

Berliner klinische Wochenschrift, March 17, 1902.

Muscular Rigidity of the Spine. R. [illegible] says that rigidity of the spine, a condition to which various authors have given different names, is not a disease *sui generis*, but is only a portion of the symptom-complex of any one of several pathological processes. The author draws especial attention to that variety which is myogenous in character and cannot be differentiated from chronic muscular rheumatism. As a rule the muscles of the thigh, back and shoulder are simultaneously affected. The clinical symptoms produced are very similar to those seen in [illegible] joint and bone lesions, but, by careful observation, the true nature of the affection can be easily ascertained. That there is no true joint or spinal ankylosis can be demonstrated by subjecting the patient to forced movements. The involved muscles are hard, tense and over-sensitive to mechanical irritation. They also frequently show muscular tremors. The muscular condition is plainly seen by using the Röntgen ray. In certain cases of long standing such muscles become atrophied, yet they show no qualitative changes to electrical stimulus. In a few cases the joints as well as the muscles are involved in the process. In such instances the joint lesions are plainly rheumatic. It should, however, be remembered that all cases of muscular spinal rigidity are not of rheumatic origin. Many are due to lesions of the central nervous system. Two cases are reported in detail as illustrative of the rheumatic variety. In such the use of baths, massage, electricity and the [illegible] is often followed by marked improvement or cure.

Acute Myelogenous Leukæmia.—Hans Hirschfeld and Willy Alexander report a case of acute myelogenous leukæmia which ran a fatal course in fourteen days and was peculiar in the fact that the eosinophiles were not increased in number and no [illegible] were ever seen in the peripheral blood. The diagnosis was made upon the clinical symptoms and the post-mortem changes in the spleen, lymphatic glands and bone marrow. The case shows that Ehrlich's contention that an absolute increase of the eosinophilic leucocytes is necessary for a diagnosis of myelogenous leukæmia is erroneous. It is, however, true that such an increase is usually present, and so far as known this is the first instance it has been wanting. From the fact that a large quantity of Charcot-Leyden crystals were found in the bone marrow, it is probable that originally an increase of the eosinophiles took place in the bone marrow, but that for some unknown reason the power of these cells to multiply was suddenly checked. The rapid fatal course of the case might lead to the supposition that a complicating sepsis was responsible for the outcome. This, however, is negatived by the fact that the characteristic septic leucocytosis was never present. Myelocytes were always present in abundance. Peculiar non-granular polymorphonuclear cells were present in from 11 per cent. to 47 per cent. These are entirely similar to polymorphonuclear neutrophilic leucocytes, except that no neutrophilic granules are seen. Their presence in myelogenous leukæmia has been observed by others. The highest total leucocyte count was 64,000. The highest temperature was 39.4°C. The pulse varied between 120 and 150.

The American Journal of the Medical Sciences, March, 1902.

Causes of Salpingitis Other than Gonorrhœal.—John B. Deaver and Edward Kemp Moore speak of this subject as having two aspects—the surgical and sociological. The causes of salpingitis other than gonorrhœal, especially noticed by the writers, are post-puerperal infection, appendicitis, and tuberculosis, and as an existing cause of acute exacerbations, minor gynecological operations. A very important etiological factor is the "terrible douche habit." The indiscriminate and careless use of the douche is deplorable. When used constantly, the vagina is deprived of its natural protection against infection. Minor gynecological operations call for much experience in the operator. Intrauterine examinations or treatment should be avoided as much as possible.

The Sanitary Measures to be Adopted after Floods.—George A. Soper states that there is need of a strong sanitary organization with a responsible head, to avoid epidemic, by removing the conditions which favor the spread of infectious diseases and to watch for cases of such sicknesses in their beginning. There should be a set of sanitary regulations issued for the guidance of the people. The scene of the wreck may be divided into sections. The people should be taught to look after their own health. Whenever a case of infectious disease is discovered, the case should be isolated and the premises disinfected. The water supply and food for the sufferers and helpers should be systematically inspected. In damaged houses slime, mould, and silt should be removed. All household stuffs should be sun-dried. Cellars should be pumped out, ventilated, and whitewashed. The most useful disinfectants will be quicklime, chloride of lime, and carbolic acid. All decomposing or decomposable organic matters and condemned articles should be burned. Human remains should be buried deep—at least six feet below the surface. An appearance of order and neatness should be observed.

An Experimental Investigation of Puerperal Pyæmia.—F. W. Gaertner describes the technique for planting thrombi infected with streptococcus or staphylococcus in the vein of a test animal. The vena jugularis sinistra of all the test animals was laid open from the place of confluence of the facial and cranial veins to the thorax, where the vena jugularis was ligated permanently, while the place where the facial and cranial veins flow together was closed only temporarily by a hæmostat, the branches of which were protected by rubber tubes, to avoid injuring the blood-vessel walls. The artificial thrombus was placed one-half inch below the ligature. The results obtained showed that the intensity of infection depended, first, from the place where the employed cocci were found (staphylococci from carbuncle pus and streptococci from erysipelas proved the most poisonous ones, no matter how many passages of their cultivation they experienced); second, from the duration of the preservation of the completed artificial thrombi before their insertion in the vena jugularis externa (the longer staphylococci and streptococci were kept in a dry state the greater was the loss of virulence, no matter how virulent the cocci proved at their first examination.)

The Clinical Significance of a Chronic Urethral Discharge.—H. M. Christian points out the common error of considering all chronic urethral discharges as "gleet." He then speaks of the three different forms of chronic urethral discharge. The first is true gleet. In this affection the urine is generally clear, containing clap shreds in abundance, which rapidly fall to the bottom of the glass, and which are microscopically seen to be composed of pus-cells, rarely containing gonococci, epithelium, mucus, and fibroid shreds. The second form is known as prostatorrhæa. The urine in all cases is clear, free from clap shreds, but is apt to contain numbers of comma-shaped, fine, hooklike shreds, which do not fall to the bottom of the glass, but float in the urine. The third form is urethrorrhæa. In this the urine is clear, invariably. A "smear," which is often impossible to obtain, consists almost entirely of cylindrical epithelium and mucus. The treatment in each of these varieties of chronic urethral discharge differs materially, so that a correct diagnosis is essential. To determine this point, the history of the case should be investigated; the macroscopical and microscopical appearance of the discharge; the effect upon the discharge of indulgence in sexual intercourse or alcohol (no effect being observed from sexual indulgence in the last two forms, while the discharge is increased in the first by this cause); and the character of the urine. The writer gives a table showing these points at a glance.

Scarlatinous Empyema of the Anterior Superior Squamomastoid Cells.—Charles H. Burnett reports the case of a girl of thirteen years, who, at the end of the fourth week of an attack of scarlatina, was brought to him on account of trouble with the left ear that had begun almost at the onset of the disease. The writer thinks the cause of the trouble lay chiefly in the treatment of the ear. It had been freely syringed with hydrogen peroxide, and the meatus firmly stopped with cotton. The mastoid region at the time of admission to the hospital was entirely devoid of any symptoms. There was a slight discharge from the auditory canal, the membrana tympani was red and macerated, and there was a slight perforation in its postero-inferior quadrant. The hearing was only slightly impaired. Just above and a little behind the upper wall of the bony auditory canal there was a prominent, pinkish fluctuating point. This was frozen by means of ethyl chloride and incised. About three ounces of creamy, odorless pus escaped, and was followed by some thinner, bloody pus. The pus had burrowed between the masseter and the buccinator. The wound was drained and irrigated for several days, but the patient's condition was not satisfactory. So a second operation was undertaken. A curved incision was made from the temporal artery, running from above and behind the auricle to the tip of the mastoid process. There was discovered an opening in the surface of the squamomastoid region slightly above and behind the bony external auditory canal, but the rest of the mastoid bone was normal. A curette was passed forward beneath the zygoma, and granulation tissue, slough, and thick, bloody pus were scraped out. A grooved director was passed from the anterior limit of the incision above the auricle down into the pus cavity on the cheek, and an incision was made from the outside at this point. The pus cavity healed from the bottom, and the aural discharge ceased entirely. Within about five weeks from her entrance into the hospital the patient was entirely well.

Archives of Pediatrics, February, 1902.

Multiple Arthritis in a Child Two Years Old Suffering from Gonorrhœal Vulvovaginitis.—George N. Acker describes a case in a child of two years, well developed and unusually intelligent. Both knees and ankles were swollen and painful, the patient crying whenever disturbed. The teeth and gums were in good condition, the tongue was coated, the heart, liver, lungs, and spleen were normal. The child was weak and exhausted, complained of pains in the head and limbs, and was sleepless and irritable when disturbed. There was a free purulent vaginal discharge. Treatment consisted of a liquid diet, 5 grains of salicylate of sodium every four hours, vaginal douches of warm saturated solution of boric acid every three hours, and the application twice daily of ichthyol ointment to the joints, followed by wrapping them in cotton. In less than a month a cure was effected.

A Contribution to the Symptomatology of Cretinism and Other Forms of Idiocy.—Henry Koplik and Jacob Lichtenstein call attention to a peculiarity in the hands of cretins, consisting in a prominence in the region of the antithenar eminence and over the situation of the pisiform bone. It is immediately adjacent to the groove which separates the palm of the hand from the forearm, and viewed from the side, rises abruptly from the above groove, giving a bayonet-like appearance. It is apparently an over-development or hypertrophy of the small muscles of the inner border of the hand, attached to the os pisiformis, as well, perhaps, as an enlarged condition of this bone itself. It is evidently not a hypertrophy caused by crawling on the floor, for it has been observed in a cretin only three months old. This stigma has been found not only in cretins but in other degenerate individuals. The authors have found it in idiots, cretins, microcephalic idiots, and children who were congenitally deficient, but not in Mongolian idiots. It was found in all cases of cretinism.

General Subcutaneous Emphysema Complicating Pneumonia.—Samuel Pierson and Walter Lester Carr report a case of this rare condition. The patient was four years and five months old, and was on the road to recovery from double pneumonia when, after a coughing attack, a swelling was noticed on the right side of the neck and face; this swelling increased until it involved all of the neck, head, trunk, and upper extremities. The child's condition became serious; he sat upright in bed, breathing rapidly, respiration, 60; pulse, 135; rectal temperature, 101°. The cough was severe and paroxysmal. The sputum was found to contain encapsulated, lance-shaped diplococci, staphylococci, and many bacilli, but no tubercle bacilli. The emphysema remained at its height for two days, during which time both [illegible] [illegible]. The swelling gradually decreased during the next three weeks and the boy was discharged cured just one month after the onset of the emphysema and [illegible] weeks after that of the pneumonia. The treatment, [illegible] with strychnine, nitroglycerin, and whiskey was directed more to the primary disease than to the complication.

The Edinburgh Medical Journal, February, 1902.

Diabetes and Pregnancy.—G. Ernest Herman reports a fatal case. The complication is a rare one, but grave when it does occur. The few cases that have been reported go to show that in intermittent cases coming on during pregnancy the prognosis is better than in cases in which diabetic women have become pregnant. Premature delivery, due to intra-uterine death of the child, has occurred in about two-thirds of the published cases. Hydramnios has been observed. Some patients have died from collapse and coma within a few hours or days of delivery. The author holds that there are strong reasons for expecting that the early termination of pregnancy will prove the best treatment for a pregnant diabetic. The child is likely to die anyway. It is possible that when the pregnancy is over the diabetic may get well, and this is more likely to take place the earlier the pregnancy ends. Moreover, the farther pregnancy be advanced and the longer the disease has lasted, the more likelihood will there be that the patient will die from collapse and coma soon after delivery.

Membranous Colitis.—Michael G. Foster applies this name to the condition in which membranes or complete casts of the bowel are at varying times passed per anum. The main features of the disease are, the passage of mucus in the form of glairy fluid, shreds or membrane, irregularity of the bowels, and abdominal pains of greater or less intensity and frequency. Most of the patients suffer from neurasthenia. There may be slight fever in each attack. In treatment, the first aim should be the treatment of the neurasthenia, by exercise and rest, plain and digestible diet, and regulation of the bowels. For the intestinal pains, bael, in drachm doses of the confection opium, during the attacks only, perhaps aromatic sulphuric acid in 20 m. to ½ dr. doses. Many patients derive great benefit from a course of treatment at the Baths of Plombières in the Vosges, the value of the waters probably consisting more in the method of employment than in their chemical composition. Warm water baths, ascending douches, and warm abdominal douches while the patient is under water are the main points in the treatment. In more hopeless cases a right-sided colotomy may have to be performed.

Annals of Surgery, March, 1902.

Misapplied Mechanical Support to Weak Ankles of Children.—H. Augustus Wilson calls attention to the mechanical imperfections of much of the apparatus sold in the market by various makers without proper surgical supervision. He says that the natural human foot best performs its functions when it is freest from restraint. It can be quickly crippled into inefficiency by high-counters, corset-shoes, arch-raisers, wedges, and elastic anklets. When burdened by misapplied mechanics, it is rendered weak, and therefore susceptible of sustaining injury, such as sprains and the formation of bunions, flat feet, wabble joints, etc. In a constitutionally weak or rachitic child it may demand mechanical aids specially adapted to the individual requirements and peculiarities of the case. Finally, it is the duty of the medical profession to discourage the indiscriminate use of high-counters, corset-shoes, elastic anklets, arch-raisers, and sole wedging, which are known to be injurious, unmechanical, and productive of permanent loss of function.

Traumatic Rupture of the Mesenteric Arteries.—A case of this nature is reported by C. J. Aldrich and is believed to be the first of its kind on record. A man fell on the sidewalk striking on the buttock and fractured both bones of the leg. During the next week he presented the symptoms of a slowly progressing internal hemorrhage, the source and location of which it was impossible to determine. Death took place on the evening of the seventh day. Autopsy showed the fracture to be in excellent condition. Abdominal section revealed a quantity of blood, the source of which was found to be from the ruptured walls of several of the mesenteric arteries. The mesentery contained an enormous amount of fat, and it is not hard to understand that the tremendous tug exerted upon this structure by the violent fall upon the buttocks was sufficient to lacerate the mesentery and produce hemorrhage. The slow development of the symptoms, occurring to death one week after the injury, is most [illegible], and the early development is to be ascribed to the slow hemorrhage and rapid absorption of the blood by the peritoneum. It is also quite certain that the vessel walls were not in normal condition, else the natural processes of repair would have closed their ruptured walls and recovery would have ensued.

Elbow Fractures in Children.—F. J. Cotton summarizes his paper in the following propositions: (1) The usual classification hardly expresses the conditions of lesion as they actually exist. (2) The lesions frequently met with are (a) external condylar fractures, (b) supracondylar fractures, (c) epitrochlear separations, (d) separation of the whole epiphysis, in the above order of frequency. (3) These forms have well marked special forms of deformity associated with them. (a) External condylar fractures frequently show the described "spur" formation with or without displacement of the condyle itself. (b) Supracondylar fractures frequently show gunstock deformity as well as backward displacement of the lower fragment. (c) Epitrochlear separations show displacement of the fragment down and forward. (4) As to loss of motion. (a) The loss of motion from external condylar fracture is rarely considerable, and is a loss of extension. (b and d) Supracondylar fractures and separations of the epiphysis may show a loss of motion due to bony displacement, usually a loss of flexion from backward displacement. (c) Epitrochlear separations may show a loss of extension apparently due to muscular shortening. (5) Ankylosis or extreme loss of motion is rare in children, is practically independent of massage or passive motion, is due to displacement of fragments and their union in displaced position. (6) Position in treatment is important only as it affects reduction and retention. (7) Treatment is to be varied to fit the lesion and displacement found, as indicated above.

Suture of the Abdominal Wall.—C. Davison believes that the ideal suture is one that can be sterilized in boiling water, will remain sterile while in the tissues, and will cease to exist when healing is finished. He says that in his abdominal work the wounds are closed by suturing each layer with a continuous silkworm-gut suture, the ends of which are left out at the angles of the wound to be removed by traction when healing is complete. The suture in the strongest layer is tied in position at each end in the layer with knots that can be unlocked by traction on the exposed end when the stitch is to be removed. He then describes in detail the various steps in suturing the abdominal wall for various purposes, accompanying his text with several excellent illustrations, and states that in general the advantages of his method are: (1) Certainty that all suture or ligature material placed in the wound has been made sterile by boiling in water, (2) Accurate layer approximation of tissue; (3) Removal of the buried sutures when healing is complete, (4) Capillary drainage from each layer; (5) Safety of intestines from injury during the application of the sutures; (6) Rapidity of application; (7) Minimum line of irritation on the peritoneal surface and consequent adhesions to the viscera; (8) Slight scar in the skin, there being no perforation of the skin by sutures; (9) All the advantages of a permanent buried suture without the danger of future irritation and extrusion of the knot; (10) The advantages of an absorbable suture without the danger of sepsis from the suture, and without producing a nidus for septic germs from the blood current during absorption.

The Journal of Tropical Medicine, March 15, 1902.

Duration of the Latency of Malaria after Primary Infection as Proved by Tertian or Quartan Periodicity or Demonstration of the Parasite in the Blood.—John T. Moore describes at length his methods of investigation, and says that the period of latency in his cases has varied from a few days to one and a half years. In a general way the latency depends upon the following, viz.: (1) It may be that, owing to a lack of development of the parasite in sufficient numbers, there is not enough toxin liberated at a time to cause symptoms; (2) The parasites may become attenuated to such a degree that they do not produce the amount and the kind of toxins to manifest symptoms of their presence, though they may be present in large numbers, (3) The individual may have acquired a certain immunity, so that he prevents a sufficient development of the parasites to enable them to liberate enough toxins to cause symptoms, or else his organism is resistent to large amounts of toxin, (4) The attenuation, lack of development or partial immunity may cause the symptoms to develop atypically, or some intercurrent disease may so modify the symptoms of malaria that they become atypical. This should be called masked rather than latent malaria.

Society Reports.

TRI-STATE MEDICAL SOCIETY (IOWA, ILLINOIS AND MISSOURI).

Tenth Annual Meeting, Held in Chicago, April 3 and 4, 1902.

The Society convened at the Great Northern Hotel, under the presidency of Dr. John C. Murphy of St. Louis, Mo.

Ligation of Arteries; Cocaine Anæsthesia was the title of a paper by Dr. B. Merrill Ricketts of Cincinnati, Ohio. The author made a plea for a more general use of cocaine for local anæsthesia, especially in operations upon the head, neck and extremities. It was more efficacious, more desirable, and less dangerous than general anæsthesia. It had a wide scope of usefulness, although as yet it had been restricted in its application. Reference was made to its application to operations of any character on the extremities, and especially to its application of those involving the blood-vessels. Cocaine anæsthesia would not only permit of the ligation of the more important blood-vessels, but celiotomy, for various purposes, as well. The removal of various neoplasms, malignant and benign; plastic operations upon nerves, cutaneous, muscular, and bony structures in a healthy or pathological state; removal of foreign bodies, or amputation of any part of the upper or lower extremities, were advised by it. Amputation at the shoulder joint, with cocaine as a local anæsthetic, had been successfully accomplished by Crile, and while there was no recorded case for demonstration, there was no reason why amputation at the hip joint should not now be accomplished in this manner.

The use of cocaine for operations was especially indicated in pulmonary, cardiac, and renal diseases; also in case of exhaustion from any cause. During unconsciousness, emergency work might be accomplished by blocking the nerve trunk; in this way further shock might be prevented, and much time saved.

The constitutional effects of a given amount injected into the head, face, and neck were more marked than when injected in other parts of the body or extremities. This was due to two causes—more rapid absorption, and its proximity to the brain. For this reason less cocaine should be used and the blood-vessels avoided.

Laryngotomy, laryngectomy, and amputation of the breast could and should be more frequently performed with the subcutaneous use of cocaine. Resection of one or more ribs could be accomplished with ease, and should be resorted to with cocaine in many conditions of the chest requiring surgical intervention.

A $\frac{1}{2}$ to $1\frac{1}{2}$ per cent. solution of the best cocaine should be secured, and the operator should know how to use it. An amount of solution containing from $\frac{1}{2}$ to $1\frac{1}{2}$ gr. of cocaine need not be exceeded in performing any operation. Subcutaneous injections alone for operations would require more of the drug than where the injections were confined to the nerve trunks. The amount of cocaine necessary for the incision to reach a nerve trunk was but a trifle more than the amount necessary for injecting one or more nerves. If subcutaneous injections alone were resorted to for operations involving more than the cutaneous structures, besides making deep primary injections, it would be necessary, now and then, to inject sensitive fascia or muscle, or both.

Dr. H. A. Leipziger of Burlington, Iowa, said that his experience in the use of cocaine for surgical procedures of importance was limited. He felt encouraged, however, from the paper to resort to local anæsthesia more frequently than he had done in the past, although his experience with it in so-called minor procedures had not been as favorable as one was led to suppose was universally the case. He had seen quite a little discomfort following the use of cocaine locally, particularly in those cases where he could not circumscribe the absorption of the drug. He thought this might have been the experience of others. The discomfort following its use might have been due to faulty administration of the drug, or to its impurity. He had seen constitutional disturbances follow the use of cocaine as a local anæsthetic.

Dr. Flavel B. Tiffany of Kansas City, Mo., had had some experience in the use of cocaine hypodermically, more especially in practising ophthalmology. He uses it in nearly all operations on the eyelid, and employs a little stronger solution than the essayist referred to. He uses about 1 per cent., as a rule, sometimes less. He almost always adds adrenalin to this, and then he gets no hemorrhage whatever. In operating for entropion, for instance, when he uses the ligature cautery, he employs cocaine hypodermically, without pain. He had never had bad results from its use in this way. He had seen more disturbance from its use when he had employed it on mucous membranes. He had enucleated eyes several times by injecting a solution of cocaine into the orbital tissue back of the eye, and sometimes he had injected the drug into the body of the eye itself with scarcely any pain.

Dr. Harold N. Moyer of Chicago said that the question of cocaine as a local anæsthetic was still *sub-judice*. He thought it would need more than the *ex-cathedra dictum* of Dr. Ricketts to settle it. Personally, he would prefer to take his chances with chloroform or ether in the hands of a good anæsthetist, rather than have cocaine injected into his spinal cord. He thought the infiltration method of Schleich had been disappointing in many respects. This disappointment was, in part, due to difficulties in sterilization, and suppuration was a common factor. In the last year or two, however, solutions of cocaine could be obtained that were sterile. One should rely on good manufacturers of the drug. Cocaine could not be sterilized by heat without destroying its efficiency. The cocaine upon the market was subject to a great many impurities, and he did not know, to-day, where to obtain absolutely pure hydrochlorate of cocaine in Chicago. Many of the untoward results of spinal anæsthesia and the local use of cocaine were due to the impurities of the drug, as well as to the difficulty of sterilization.

Dr. Ricketts, in closing the discussion, condemned spinal anæsthesia, saying that he had never had the courage to resort to it. The experimental work of Crile had shown degeneration of the cord, which was sufficient to condemn it. As to the use of adrenalin, there were some advantages to be obtained from combining it with cocaine. He had amputated the thigh, the leg, the forearm, the breast; had done herniotomies; had ligated the femoral in Hunter's canal, with cocaine, in the manner described in the paper.

The Technique and Possibilities of Endo-Vesical Operative Procedures.—Dr. Louis E. Schmidt of Chicago read a paper on this subject. He mentioned the important points in connection with operative cystoscopes, and showed their differences.

1. Nitze operative cystoscope. Here the lamp, prism and window are on the concave surface of the beak. In front of the space, between the lamp and the window, the operative appliances are placed. The operative appliance carries in its hollow shaft the optical apparatus The latter is moveable, so that the operative appliance can be brought to different distances and positions from the cystoscope part. These mechanical appliances are the galvano-caustic snare, cautery, small forceps and lithotriptic forceps.

2. The Casper operative cystoscope differs from the Nitze instrument in that the lamp, window, and prism are on the same plane, so that the whole optical apparatus is straight. The operative part is practically similar to the Nitze. Both of these cystoscopes compel the operator to work under indirect vision.

3. With the Kolischer operative cystoscope the operator works under direct vision. The lamp and window are situated on the convexity of the beak. A canal is attached to the under part of the cystoscope, through which the

[illegible] instruments and [illegible] into the bladder. [illegible] and appears just below and in front of the [illegible].

Considering the merits and demerits of these types, the views of the Nitze instruments [illegible] Kelly and Casper, [illegible] the operative appliance and [illegible]. The Nitze cystoscope has the advantage of direct view, and in consequence of its construction the working ends of the instruments applied do not interfere with the clear view of the field of operation.

Most of the endovesical operations can be done under a carefully given local anesthesia. There is great danger of perforation of the bladder. As a good anesthesia a highly concentrated antipyrin solution is to be recommended. It requires [illegible] minutes [illegible] gives the desired effect. The bladder should be [illegible] distension.

Previous to any operation it is always advisable to have the bladder in as good a condition as possible, so that the usual irrigations, instillations, and internal medications can be employed. This procedure not only causes the bladder [illegible] condition, but also brings the localized centers of the pathological changes into prominence. One of the most frequent indications for this method of treatment is stubborn cystitis. Under this are comprised not only the inflammation of large areas, but also small localized infiltrations, as fissures, ulcerations, remnants of cystitis, where the adjacent parts are free from pathological changes. Fissures located at the neck of the bladder can be healed with a single treatment, consisting of cauterization. Ulcers of the bladder, following gonorrheal cystitis, can be successfully treated by the aid of cystoscopy. The coating and granulations which cover the ulcer must be thoroughly curetted, and prompt cure follows. Varicose [illegible] of the superficial veins, which give rise occasionally to severe hemorrhages, are easily removed by cauterization with the galvano-cautery. Foreign bodies of considerable size in the bladder should not be removed by means of the operating cystoscope, on account of the unnecessary traumatism. The operating cystoscope plays an important rôle in the after-control of lithotomy.

Prenatal Syphilis.—Dr. Ohmann-Dumesnil of St. Louis, Mo., detailed a case of prenatal syphilis. He condemned the use of the word hereditary or congenital syphilis. He preferred to use the word prenatal, believing that it is more comprehensive, and more clearly defines the condition which exists.

Sporadic Infantile Myxœdema Resulting in a Cretinoid Condition.—Dr. James Frederick Clarke of Fairfield, Iowa, reported a case of this disease. The patient was twenty years of age when first seen, and a marked imbecile of typical cretinoid condition. The family history was negative. The degeneration began at the end of the first year, and was shown by a series of photographs taken every few years through life. Thyroid feeding for the [illegible] months had showed an increase of two and three-quarter inches in height and a marked transformation as to intelligence and physiognomy. This was illustrated by a series of photographs taken every two months during treatment. The patient has been taking thyroid tablets, equal to [illegible] grains of fresh gland, every day.

Dr. Frank P. Norbury of Jacksonville, Ill., said he saw a boy, nine years of age, in consultation in 1895. The child was fed on thyroids. The result was satisfactory and pleasing. He said the results of thyroid feeding had been satisfactory in the treatment of such cases.

Pathological Specimens.—Dr. Isaac A. Abt of Chicago exhibited some interesting pathological specimens, and among them, a specimen of diaphragmatic hernia from an infant, adenoma of the cerebellum of the right side from a child six years of age; intussusception from a baby twenty-one months old; a picture of the brain and spinal cord from a case of epidemic cerebellar spinal meningitis, [illegible] of the [illegible] of twenty-one months old baby, and a photograph showing the condition of a spina bifida during life.

Cholecystectomy Versus Removal of the Mucous Membrane of the Gall-Bladder.—Dr. Emil Ries of Chicago presented a paper with this title. The author confined his remarks principally to two methods, cholecystostomy and cholecystectomy, the former a method practised by Kehr and Mayo, consisting of inserting a rubber tube into the contracted gall-bladder, making the opening in the gall-bladder water-tight by applying a suture around the rubber tube. This operation afforded drainage of the gall-bladder, and through it the tract, for a considerable time, but it was not without objections, and Mayo, in a paper on the removal of the mucous membrane of the gall-bladder, mentions the main objection to this method. As an emergency operation, cholecystostomy was satisfactory, but as an ideal method it was not. A second operation which he considered in comparison with cholecystectomy was Mayo's operation of removal of the entire mucous membrane of the gall-bladder without removing the entire gall-bladder. While this operation seemed very reasonable, and it had been performed by Mayo and others with success, the author stated that, according to some recent observations in surgical pathology of the gall-bladder which he had made, the operation was open to serious objections. He then reported a case which he operated upon three months ago. The patient was a woman, forty-five years of age, who had passed gallstones several times in her life, first when she was eighteen years of age, then two years ago, and within six months before he operated, quite frequently. She had never been jaundiced. The stones varied in size. She had not been free from pain for the last two years. The liver was not enlarged, the region of the gall-bladder was painful on pressure. Operation showed a very small, contracted, adherent gall-bladder. There were adhesions between the gall-bladder and the upper end of the duodenum, gall-bladder and omentum, gall-bladder and colon. The gall-bladder was found to contain gallstones. He peeled off the gall-bladder from the liver, after cutting through the peritoneal coat, down to the common duct, removed the gall-bladder with the cystic duct, and closed the stump with catgut sutures. He sewed the muscular coat of the cystic duct together, took a long piece of omentum, stitched it over the suture in the cystic duct, to serve as a drainage, and then passed a strip of gauze down to the stump. This completed the operation. The patient recovered.

The glands of the mucous membrane of the gall-bladder were tortuous and hypertrophied. They did not show normal epithelium throughout. Most of the cells of the glands were of a high cylindrical type with nuclei about the center of the cells. There were areas of round-cell infiltration throughout the mucous membrane. The most important observation was this: Elongated glands passed right through the muscular coat clear down into the connective tissue in numerous places. He had examined 150 sections from various parts of the gall-bladder, and had found this condition in numerous places. The thought struck him that if anybody attempted to remove the mucous membrane of the gall-bladder alone, he would doubtless fail. He had never been able to learn whether Mayo had ever had the mucous membrane of the gall-bladder, which he had peeled off, examined microscopically or not. He thought it was impossible to remove the mucous membrane of the gall-bladder alone. His recent pathological research work had convinced him that the operation of peeling out the mucous membrane of the gall-bladder was a step in the wrong direction, and that it was liable to be followed by more trouble. He, therefore, advised strongly in favor of cholecystectomy rather than stripping off of the mucous membrane of the gall-bladder.

Plastic Surgery in Ophthalmology.—Dr. F. B. Tiffany of Kansas City, Mo., read a paper with this title. He spoke of the use of large skin grafts to restore destroyed lids by lupus, burns, cancer, etc., taken from remote parts without a pedicle. These grafts embrace the entire skin, and they are transplanted directly without being passed through any medium, and put upon a granular surface, where they grow without sloughing.

In cases of distichiasis and trichiasis that have been previously operated on, and there is no integument to spare, von Milligan's operation is recommended, which consists in splitting the edge of the lid at the mucous line and transplanting a strip of mucous membrane from the lip of the patient, vagina, or from the conjunctiva of a rabbit's eye. In ordinary cases of entropion he uses the electro-cautery, incising the integument near the margin of the lid from one canthus to the other, two or three millimeters distant from the margin of the lid; then, from cicatrization the margin of the lid is turned away, correcting the entropion. For ectropion he makes a similar operation, cutting with the electro-cautery the conjunctiva from near the punctum of the outer canthus at a distance of two or three millimeters from the margin of the lid. Sometimes he makes two or three longitudinal incisions. If more than one or two, a third is made at the retrotarsal fold or culdesac. Probably 95 per cent. of all cases that have come to his clinic and private practice of entropion and ectropion within the last three years have been corrected by electro-cautery treatment.

For congenital ptosis, where there is absence of the levator palpebræ superioris, he makes Panas' operation, which gives better results than any other operation that has ever been made up to the present time. The steps of this operation were described.

Pictures were presented of the case of a boy, ten years of age, with complete congenital ptosis, in whom there was the absence of the levator palpebræ superioris of each lid. The result was excellent, as shown by the photograph taken subsequent to the operation.

Differential Diagnosis of Smallpox.—In a paper on this subject, Dr. J. C. Sullivan of Cairo, Ill., impressed the point that whenever we have a patient complaining of severe and persistent backache, followed by fever and a pustular eruption, affecting the palms of the hands and the soles of the feet, protruding from beneath the outer skin, we have a case of smallpox to deal with, no matter how insignificant or mild it may appear, and a case of confluent or even hemorrhagic smallpox may be contracted from it. Hence the necessity of immediate vaccination of all parties exposed, and of strict quarantine or isolation in each case. There were but two diseases that produced this phenomena, namely, syphilis and smallpox. The former should not be confounded with the latter, as a history of chancre would suffice for the differentiation. From measles it may be differentiated by Koplik's sign, when found, which consists in the appearance of little white pearly bodies on the inside of each cheek before the faucial redness of early measles. The typical lobster rash, strawberry tongue, and persistent white line of that most eccentric of all diseases, proclaimed scarlet fever; a multiform punctated and individual crescentic rash, that of rotheln; the successive crops of vesicles affecting the shoulder-blade, probably chickenpox. A pustule stuck on the surface of the skin, impetigo, lichen planus, and papular eczema may be at first confounded with smallpox; but the pustular eruption of the palms of the hands and soles of the feet makes the diagnosis of smallpox positive. The essayist did not believe there was such a disease as Cuban or Porto Rican itch. The adherents of the theory of a third or intermediate disease similar to rotheln, measles, and scarlet fever, have strongly fought the idea that modified smallpox could be a true disease, still, by repeated examinations and diagnoses the most eminent specialists have named it smallpox. Many admit its contagiousness, but fail to quarantine. In this respect they err, for when a disease, no matter what its name or nature, is contagious, and before it becomes endemic or epidemic, it is the duty of every physician to report it to the health authorities, and work in concert with them to see that it is at once quarantined until all danger of its communication to others shall have passed.

Conglomerated Cystic Kidney.—Dr. J. F. Herrick of Ottumwa, Ia., read a paper on this subject. The patient was a clergyman, forty-five years of age; Irish nativity; of good habits. Always well, except for a fall from a street car in April, 1899. Taken January 20, 1901, with an attack of unconsciousness. Was up and about in three days. Urine, eight pints in twenty-four hours; specific gravity, 1005; small amount of albumin; few hyaline casts; no pus. Diagnosis, contracted kidney. On April 1, 1901, a nodular tumor was found in region of each kidney. Under treatment and milk diet, urine, four pints; specific gravity, 1010; some albumin; few hyaline casts. Diagnosis changed to conglomerated cysts of kidneys. August 12, 1901, was taken with diarrhœa. August 19, he became stupid. August 21, comatose, and died on August 22. Large nodular tumor in region of either kidney. Autopsy revealed mass of cysts, weighing about four pounds, in place of normal kidney. Cysts ranged in size from millet seed to crow's egg. Suprarenal glands enlarged. No normal kidney substance could be seen. No other abnormalities discovered.

Ligation of Common Iliac or of External and Internal Iliacs Preliminary to Amputation of Lower Extremity at Hip Joint.—Dr. Augustus C. Bernays of St. Louis, Mo., presented a paper with this title. He said that in many cases Senn's and Wyeth's methods left much to be desired, if it seemed necessary to save the patient from even a small loss of blood. He reported an operation and presented photographs of a case of myxosarcoma of the thigh, reaching above Poupart's ligament, in which the ligation of the common iliac enabled him to perform an almost absolutely bloodless operation. The ligation was done through a small abdominal incision, made exactly over the brim of the pelvis on the affected side. Dr. Bernays claimed that the aseptic ligation of the iliacs could in no way add to, but would not likely lower, the percentage of mortality in those cases in which the ablation of the lower extremity was indicated. He strongly recommended the method in suitable cases. His patient recovered in a few weeks.

Hemorrhage After Tonsillotomy.—This paper was read by Dr. H. A. Leipziger of Burlington, Iowa.

Tonsillotomy is one of the so-called minor operations, which becomes a very formidable one in case of hemorrhage. Even if there is no fatality, the apparent danger, continuance of bleeding, and frequently the inability of the surgeon to arrest the same create a degree of anxiety for doctor and patient, and a liability to censure and reproach for the doctor alone, which should stimulate all surgeons to cease regarding the operation as minor. The patient should be informed of the dangers, and examined at least as carefully before operation as before a life insurance examination, which never involves more than a limited amount of money. Authors refer to fatal cases, but the writer could find no reports of a fatal case in the *American Journal of the Medical Sciences* from 1827 to 1902, nor in other literature at his disposal. Bosworth could not find a case reported which he would consider authentic. Very recently an abstract appeared (*Journal of the American Medical Association*, March 29, 1902), making reference to five fatal cases recorded, two of which were children. The operation should never be done in the doctor's office, but by preference in a well-appointed hospital. Bleeding will follow a tonsillitome as well as a knife. The common advised styptics and methods of arresting the bleeding do so when the bleeding is insignificant; when it is severe they all fail; even tying the common carotid has failed. There seems to be underlying the parenchymatous oozing some nervous or vaso-motor influence which is excluded by syncope or unconsciousness

The [illegible] relieved by hypodermics of morphine, which were used in the writer's case with sufficient effect to make him believe it arrested the [illegible] when all other means had failed.

Psychology as Applied to Modern Medicine.—A paper with this title was read by Dr. G. H. [illegible], of Washington, D. C. He referred to the delusions under which a large number of people were laboring. The sudden rise and rapid spread of the religious vagaries and [illegible] taught by Mrs. Eddy, Dowie, Schlatter, Schweinfurth and others afforded abundant evidence of that fact. The whole history of Christian Science, Dowieism, Spiritualism, and Osteopathy formed curious chapters in the mental history of our age.

How to counteract these modern unwholesome tendencies was the question. Criticism would not do it. Ridicule would not suffice. Such movements were strengthened by denunciation. They fattened on persecution. He thought the deathblow to all such scientific, philosophic, and religious vagaries was struck when the truth was shown concealed behind the fallacy. It was at this point that medicine had failed in the performance of her duty. While Christian Science had swung to one extreme, medicine had swung to the other. If the followers of Mrs. Eddy had laid sole emphasis on the psychical, ignoring the physical, the physician, on the other hand, was tempted to confine himself to the physical, leaving out of account the mental. Had physicians studied the psychic side of life, as they ought to have done, applying psychological principles to the treatment of disease, there could be no reasonable doubt that much could have been done to counteract those delusions which were to-day spreading with such alarming rapidity. Why should the physician leave this interesting and important field to the untrained quack, that he might make of it a matter of merchandise? That many human ailments were of mental origin, and could be healed by purely psychological means, there could be no question. Into many others the psychical entered as a very important element. This being so, in order to successfully treat the human body one must know something of the human mind, its laws, and methods of working. Without this knowledge, accurate diagnosis of disease, in some instances, was impossible. When carefully diagnosed it might turn out that the patient needed the good offices of a clergyman, a psychologist, or neurologist. At all events, the physician must be able to make the diagnosis, whoever effects the cure.

Man was something more than a bundle of nerve cells, bones, blood vessels, and various kinds of tissue. Therefore, the successful practitioner must interest himself in something besides physical symptoms and matters of organic function. So long as man is made of body and mind, so long as these continue to influence one another, just so long would the study of the psychical side of human nature be a valuable part of the equipment of him who ministered successfully to its physical side. That a new emphasis would be put upon the psychological element in the future, the author had every reason to believe. It was his [illegible], arising from a conception of the profound need of such investigation, that the time was ripe for a forward move in this direction.

Acute Delirium.—By Dr. FRANK P. NORBURY, of Jacksonville, Ill.

He said that acute delirium was an etiological problem, one upon which the leading authorities did not agree. It might not be regarded as an entity, but a combination of pathological conditions, chief of which was an encephalitis, more or less intense, and almost invariably fatal. The tendency of late was to regard the disease as an infection, but as yet no pathogenic bacteria family group had been isolated. The Russian school, following the lead of the Italians, had made reports conclusive in their deductions, endorsing the infection theory. From a clinical study of three cases, one of which came to autopsy, Dr. Norbury endorsed the infection theory and held that the disease was comparable in its clinical history to [illegible] of the [illegible]. The question of differential diagnosis was aided by laboratory methods.

Diagnosis of Cancer of the Breast.—Dr. ALFRED [illegible], of St. Louis, Mo., read a paper with this title. He said there was no doubt that in its early stages every cancer of the breast was a strictly localized condition, and that its successful treatment depended entirely upon early diagnosis and immediate radical extirpation of the malignant focus. In advanced cases the diagnosis was easily made, but in the early stages it was often exceedingly difficult to distinguish cancer from abscess, syphilis, tuberculosis, various cysts, and the benign tumors. Text-book distinctions did not hold in practice. The diagnosis can only be made after most thorough physical examination and a searching investigation of the case history. While the microscope is a valuable aid to diagnosis, it occupies a place of secondary importance.

The differentiation of the various tumors of the breast was briefly discussed.

Multiple Neuritis.—In a paper on that subject, Dr. DANIEL R. BROWER, of Chicago, said that the diagnosis of multiple neuritis in its classical form was very simple, but at the bedside there were but few classical cases, so that errors in diagnosis were not infrequent, and as the prognosis of multiple neuritis was usually favorable under proper treatment, and the prognosis of the diseases with which it was usually confounded was very bad, a correct diagnosis was of great importance. The disease was the result of some kind of poison, and while the action of this agent might be limited to the peripheral portion of the neurone, yet there were cases in which the cell body was as well impaired, and this also created confusion in diagnosis. The principal poisons producing a multiple peripheral neuritis were alcohol, lead, arsenic, and the toxins of the various microorganisms, especially those that produce diphtheria, influenza, typhoid fever, gonorrhœa, syphilis, leprosy, and beriberi.

In the typical cases of multiple neuritis there was symmetrical localization of motor, sensory, and vaso-motor symptoms. In the earlier stages the symptoms were the result of irritation of the nerve, while the later symptoms were those of destruction. In the beginning there were muscular cramps and spasms, shooting pains, and paræsthesia. Later on, paralysis and anæsthesia.

The diagnosis of alcoholic neuritis was based upon the evidences of chronic alcoholic poisoning, found in the digestive, circulatory, and nervous systems. The onset was usually insidious, weeks or months being necessary for its full development. The earlier symptoms were numbness, tingling, muscular cramps, tremors, and vasomotor disturbances, such as cold or clammy hands or feet, or a hot and burning sensation in the same extremities. In a few cases there was marked psychic disturbance.

Arsenical neuritis very much resembled alcoholic neuritis. The differentiation from alcoholic neuritis was made in the few cases he had seen by the absence of any evidences of alcoholism, by the œdema of the eyelids, pigmentation, epigastric pain, and [illegible]. These cases were the result of the continued use of large doses of Fowler's solution, and the tremors were more marked than in alcoholic neuritis. The knee-jerks and typical reflexes were present. Some cases were the result of the combined action of alcohol and arsenic, as evidenced by the remarkable epidemic that occurred in Manchester, England, in 1900, from beer. The source of arsenic was traced to sugar used in brewing. Recent investigation by Ross would seem to indicate that arsenic may be the principal etiological factor, although hitherto it has been regarded as microbic. The treatment of the several forms of neuritis had, in common, rest, the relief of pain and insomnia; also, in the early stages, the constant galvanic current of low amperage, applied daily to the nerve trunks involved, was of use, together with and attention to elimination by skin, bowels, and kidneys. The alcoholic patients required the bromides, with codeine in such doses as was necessary to secure a reasonable degree of comfort, also the use of nerve tonics, of which strychnia was the most serviceable. In alcoholic neuritis it was very essential to withdraw at once, and entirely, alcoholic stimulants. In the treatment of beriberi, it was the opinion of physicians who had had much experience with the disease that the patient must be moved from the locality where the disease was contracted, must have absolute rest in bed, mild laxatives, diuretics, tonics, and anodynes. When cardiac failure seemed imminent, strychnia and nitroglycerine had given the best results. After the acute stage of the several forms of multiple neuritis had passed, the patients required vigorous restorative treatment.

The diet throughout must be carefully regulated to suit the digestive condition of the patient. As soon as the acute pain had disappeared, the use of the galvanic current of a proper amperage, interrrupted, so as to produce muscular contraction, was indicated. The seances should be short; not more than three or four contractions of each group of muscles should be made daily with a current of the least possible amperage. Gentle massage should be commenced at the same time the electrical exercise of the muscles began, and the severity of this treatment should be increased as muscular soreness subsided. This exercise of the atrophied muscles would ordinarily result in their slow redevelopment, and after a time they would respond to the faradic current, and then it should be substituted. Much benefit may be had by the hypodermic use of strychnia, a daily injection, beginning with 1-60, and gradually increasing it to a full physiological dose. If the case did not yield, hypodermic injections of the chloride of gold and sodium, gr. 1-24, might be added to the daily treatment. As soon as possible, the patient should be encouraged to make voluntary muscular movements frequently. In the beginning of treatment many cases of multiple neuritis were discouraging, and the physician was apt to consider them hopeless too soon. Some of the most satisfactory results he had obtained were in cases of long-standing neuritis, which had been abandoned by physicians as incurable.

Intemperance and Life Insurance.—Dr. C. F. Wahrer of Fort Madison, Ia., contributed a paper with this title. He said that insurance companies had made careful estimates of the factors entering into the product of life insurance. They excluded the intemperate, the vicious, the debauched, persons suffering from chronic diseases liable to terminate fatally, those engaged in hazardous occupations, and the extremes of age. Some companies had created a department of sub-standard risks, whom they insured conditionally, such as those dying within a given period pay higher premiums, and forfeit a portion of their policies, but if they live beyond the stipulated time, their policies become standard. Other companies protected themselves by stipulating that if the insured died on account of these faults already mentioned, he forfeited his policy.

The author held that despite many conflicting opinions, as regards the use of alcohol, one thing was certain, and all scientists agreed that even its moderate use was not beneficial and might easily be harmful, and that all insurance companies regarded drinkers as belonging to the class of hazardous risks.

Drinkers easily fell victims to such diseases as nephritis, heart disease, pneumonia, typhoid fever, and cirrhosis of the liver, and since intemperance was most frequently found among the lewd and vicious, they were particularly liable to gonorrhœa and syphilis. Once attacked, their chances for recovery were greatly lessened by the life they had led. Men following hazardous occupations were liable to injuries, and if intemperate they stood operations poorly, and their chances for recovery were relatively small.

Since intemperance played such an important rôle in life insurance, it was well to note the fact that the children of drinkers were poorer risks than those whose ancestors had led pure and temperate lives. There were two kinds of risks: The standard, embracing those who passed a satisfactory examination and received an unmodified policy at usual rates; and the sub-standard, who, on account of an unsatisfactory examination, were given a modified policy.

The author suggested the establishment of a new class, the super-standard class, in which, beside possessing the good qualifications of the standard risk, the applicant must be a *teetotaler*. He thought it just that these should not pay for the shortcomings of others, and that there was a sufficient number of them to justify the creation of a separate class to whom policies should be issued at reduced rates.

Treatment of Malignant Tumors by the X-Ray.—Dr. Wm. Allen Pusey of Chicago read a paper on this subject, illustrated by stereopticon. This paper attracted more than ordinary interest. Excepting a few epitheliomas, the whole list represented cases which had baffled as skillful men as the country possesses, or had been passed upon as hopeless by masters of the profession. A more unpromising group of cases could hardly be imagined. The cases were presented for what they were worth, that each one would give them whatever weight he considered they were entitled to. The author stated that the *x*-rays had a destructive effect upon tissues of low vitality, and that this effect can be utilized under suitable conditions to cause the destruction of such tissues without destroying the involved healthy tissue. His sections showed that the *x*-rays cause a degeneration of some sort of carcinomatous tissue and a disappearance of it presumably by absorption. This disappearance of carcinomatous tissue was followed by the formation of firm healthy scar tissue. A simple process presumably occurred in the disappearance of diseased tissue in tuberculosis, sarcoma, and pseudo-leukemia. The advantages of the *x*-ray method were that it was painless; it destroyed diseased tissue, but left the healthy tissue in its place. It left small scars, and it could be used in cases in which the surrounding healthy tissue could not be sacrificed. It was available for cases in which ordinary methods involve extensive operation and serious subsequent disfigurement, as, for example, about the eye and nose. It was available in cases in which ordinary methods were impossible, because of the amount of destruction of tissue which complete removal would require. It was applicable to many inoperable cases. It often relieved pain. The use of *x*-rays should, in his opinion, be limited to those cases which, for any reason it is inadvisable or impossible to treat by ordinary methods. He does not advise the use of *x*-rays as a substitute for operations in operable malignant growths. As regards cutaneous carcinomas, he believed no strong objection was to be found to the use of *x*-rays as a primary method of treatment, and some advantages were to be urged for it. All other malignant neoplasms should have the advantage of operation where it was practicable. With the present evidence of the effect of *x*-rays upon malignant neoplasms, he believed he was justified in maintaining the following propostions: First, in all cases of malignant disease which had been operated upon there was reason to urge the subsequent use of *x*-rays as a prophylactic measure. Second, in all inoperable cases of malignant disease the use of *x*-rays should be tried. Third, in all such cases there was a probability of relieving pain and a possibility of inhibiting the progress of the disease.

Medical Education.—This was the subject of the President's address, which was delivered by Dr. John C. Murphy of St. Louis, Mo. The vital factors in medical education, he said, were the teacher, the student, and the college. A man who aspired to teach others should himself have a thorough understanding of what he attempts to teach, and should be chosen on account of his specia knowledge of some particular subject, [illegible] in the college. He had known instances where a [illegible] would [illegible] of chemistry or biology and [illegible] full-fledged professor of gynecology or abdominal surgery. [illegible] with such versatile talents as to make him equally successful [illegible] all these. [illegible] greatly and could not be accomplished by any short cut [illegible]. It is only by concentration in some particular channel that one can hope to become a [illegible] among his [illegible] and rise above mediocrity.

The medical teacher should have a proper preliminary training. No man can hope to turn out a finished product unless he himself is finished. If his work is well done, as he approaches the end of his career, and takes a retrospective glance down the vista of his life, he sees here and there many intellectual giants of his own creation, ready to continue the work he has so well begun, to perpetuate his name, and [illegible] and transmit the heritage of progress.

"The medical student is the very center of the arch, the keystone of the structure, without which all must fall. There are avenues with many opportunities for the earnest worker along the various avenues of science, but there are none which offer greater opportunities for reward than the science of the saving of human life. Men should be famous for the good they do to others. There are more heroes in the medical profession than in all the armies of the world; men who every day risk their lives amidst scenes of pestilence and disease that others may live. The man who goes forth to wage war on disease is a greater hero than Alexander the Great or Julius Cæsar."

He would say to the prospective medical student: "Let him think well of what he is about to undertake. Before he begins to dissect others, let him, metaphorically, dissect himself, and see if he possesses the moral and intellectual attributes necessary to success." A proper preliminary education is as requisite to the student of medicine as is a fertilizer to the soil.

This country could boast of some of the greatest medical centers in the world, but, unfortunately, it possessed some of the poorest. It was not necessary for the welfare of humanity that every village and hamlet should have a medical college. In the speaker's mind, the medical college should not exist as a separate and distinct institution, but should be a department of a university for general education. The science of medicine and surgery, while it had almost reached a perfect stage, still had many hidden mysteries yet to be revealed.

The course of four years in college is to the student what the period of prenatal existence is to the infant, a time of development and preparation for an independent life. What does the term Alma Mater signify but loving mother? If we would have our children be a credit, we must have a care as to the kind of material we select for their making. We must not be like the fishermen who let down their seines and gather in all that are caught in their meshes. Unfortunately, too many colleges pursue this method and cast their nets in the form of enticing literature to tempt the smith from his forge, and the husbandman from his plow, where nature intended them to remain. They come, they see, but they conquer not. Their cherished hopes are blasted; their desires unsatisfied, their time wasted. All they have to show for their endeavors is a worthless piece of parchment bestowing a worthless title. The great percentage of them must go back to the forge and the plow or starve.

Cataract Operation in the Very Old.—Dr. A. B. Hale of Chicago read a paper on this subject. He spoke of trying to overcome the prejudice among the laity against cataract operation in the very old. The eye was more amenable to surgical interference in these cases than other organs of the body.

His conclusions were: (1) Tissues of the old [illegible] and the [illegible]. (2) Vision need not necessarily be impaired. (3) Patients stand the operation surprisingly well, and with little reaction. (4) Every case of cataract in the very old, if the retina and nerve seem to functionate well, should be given the chance of operation. (5) Emergencies should be anticipated and met at once as they arise. (6) Repair proceeds slowly, but as securely as at an earlier age."

Splanchnoptosis.—Dr. Fred Byron Robinson of Chicago made a few remarks on this subject, which were illustrated by beautiful charts.

Tetanilla.—Dr. J. W. Hanna of Winfield, Ia., detailed a case of tetanilla which came under his observation. He said that this name was applied to a peculiar neurosis, characterized principally by paroxysmal tonic convulsions of certain groups of muscles. The disease attacked by preference children and young adults, varying in age from fifteen to thirty, yet he was inclined to believe that the disease attacked persons of any age. The cause or causes producing this affection were not well understood. His patient was a farmer, fifty-five years of age.

The Hygiene of the Pregnant and Puerperal State.—A paper with this title was read by Dr. C. E. Paddock of Chicago. During the puerperium no arbitrary rule could be established regarding the time the patient might get up. The character of the lochia should be the guide. As involution advances the lochia changes, and when all odor had ceased, and the lochia but scanty or none at all, the patient can begin to get up slowly. This change might occur in a week, or several weeks. The patient was neglected during pregnancy, and the puerperium by the busy general practitioner. The physician who carried out a systematic treatment of his cases had fewer mortalities and fewer conditions of morbidity.

Dr. Florence Patrick of Burlington, Ia., followed with a paper in which she covered essentially the same ground as that outlined in the paper of Dr. Paddock.

Infections of the Puerperal State and Their Surgical Treatment.—The author of this paper was Dr. Emory Lanphear of St. Louis, Mo., who said that the fatality from cases of puerperal infection attended by midwives was appalling. The mortality arose from several things: First, non-familiarity with the various causes of puerperal infection. Second, inappreciation of asepsis. Third, procrastination. Fourth, meddlesome interference with natural processes. Fifth, the spread of venereal diseases.

He dealt largely with non-familiarity with the causes of puerperal infection. The normal vulva constantly contained myriads of bacteria, pathogenic as well as innocent, which might be introduced into wounds of the genital tract by careless methods. The normal vagina of the pregnant woman did not contain any pathogenic microorganisms, hence autoinfection is not a possibility in natural labor. The vagina contained innumerable forms of non-infective bacteria, but these disappear at the cervix, no microbes ever being found in the cavity of the uterus under natural conditions. The secretions of the cervix uteri, as well as, to a less degree, those of the vagina, possess mildly antiseptic powers, so that, unless an unusually large number of virulent organisms be introduced, infection is not apt to occur.

He spoke of ten varieties of infection, and reported several cases illustrating the different types of infection. He had been disappointed in the use of Marmorek's serum in the treatment of puerperal infections. Women in labor should be treated upon the same principles and rules of antisepsis and asepsis as governed surgeons in the most extensive operations.

The Pathological Status of Retroverted Uteri.—Dr. Wm. A. Tichenor of Chicago read a paper on this subject. The author thought there were certain grave pathological conditions found in the uterus and adnexæ, in which the first step was backward displacement. Among the more grave is prolapsus. Practically all cases of prolapsed uteri were first displaced backward, for it was practically impossible for a uterus to slide down the vaginal canal if the cervix was well back toward the sacrum, and the fundus well up against the pubes. In this position the organ was across the axis of the vaginal outlet, and would not prolapse; but when the fundus was in the hollow of the sacrum the organ was in the most favorable position for gravitating toward the vaginal outlet. The retroverted position militated against the expulsion of menstrual and other secretions. This position retarded venous circulation, thereby favoring the growth of any pathogenic bacteria that might find lodgment. It lessened the woman's ability to bear children by decreasing the chances of conception, and increasing the chances of abortion. He thought about one-third of all gravid uteri abort. The retrodisplaced uterus was a prominent etiological factor in prolapsed ovaries. Retroverted uteri and prolapsed ovaries were in the most favorable position to be irritated and injured by the passage of hard fæces and during the act of coitus.

He did not attribute that importance to an uncomplicated case of retroversion without pelvic symptoms in a young unmarried woman that had generally been given to it in the past few years. If the subject was a young unmarried woman, and without symptoms, he would advise against local treatment, looking after the general health, and suggesting the assumption of the knee-chest posture night and morning. But if the patient showed decided symptoms that were distressing and referable to the pelvis, he would advise mechanical and medicinal measures.

To correct malposition of the uterus, he would first endeavor to relieve congestion and tenderness, if present, by boroglyceride tampons and hot vaginal douches After this he would replace the uterus by careful bimanual manipulation. To attempt to replace a uterus by a sound or other intrauterine instrument was reprehensible; it might possibly require several seances before the organ was completely restored to its normal position. When this was accomplished he would try to retain the uterus in anteversion by a well-fitting pessary. Before attempting to use a pessary to retain the uterus in anteversion the organ should be freely movable, not sensitive to the touch, and the ovaries should not be where a pessary will press upon them. With due consideration of these points, and using a pessary of proper shape and size in each case, the use of the pessary would prove very satisfactory.

The author then considered cases of retroposed uteri accompanied with other pelvic troubles, and discussed the Alexander operation, also the comparatively recent operations devised by Dr. Alexander Hugh Ferguson, and Dr. J. Clarence Webster of Chicago.

Dr. Frank P. Norbury submitted a revised report of the Constitution and By-Laws in conformity with the plan of reorganization of the American Medical Association, which was adopted.

Dr. Fenton B. Turck of Chicago offered a resolution, that dietetics, hydrotherapy, and mechanical physical therapeutics be taught by practical methods in the medical schools of the United States, which was adopted,

Officers for the Ensuing Year.—*President,* Dr. Alexander Hugh Ferguson, Chicago; *First Vice-President,* Dr. Flavel B. Tiffany, Kansas City, Mo.; *Second Vice-President,* Dr. J. C. Sullivan, Cairo, Ill.; *Secretary,* Dr. W. B. La Force, Ottumwa, I.a; *Treasurer,* Dr. Emory Lanphear, St. Louis, Mo. Place of meeting, Hannibal, Mo.

Curious Cigarettes.—Coffee cigarettes are the latest form of smoking. They are supposed to cure a person of the smoking habit. The cigarette is made of the leaf of the tree, not a compound of the ground bean. Coffee-leaf smoking is said to possess the property of imparting to smokers an intense dislike for the flavor of tobacco.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Sewage and the Bacterial Purification of Sewage. By Samuel Rideal. 8vo, 308 pages, illustrated edition. John Wiley & Sons, New York. Price, cloth, $3.50.

Progressive Medicine, Vol. 1, March, 1902. By Hobart Amory Hare, M.D. 8vo, 462 pages. Lea Brothers & Co., Philadelphia. Price, $2.50.

A Study of the Nervous Complications and Sequelæ of Pneumonia.—Charles J. Aldrich says that the neural element of pneumonia is written large. Pneumonia often follows injury to the pneumogastric nerve, or affections of the basal ganglia of the brain, and is a common termination of meningitis, brain tumor, and apoplexy. Neuralgia has been observed preceding and accompanying pneumonia. Among the other nervous complications and sequelæ of the disease are herpes zoster and ophthalmicus, convulsions in children, hiccough, chorea, tetanus, and trismus, color blindness, aphasia, priapism, affections of the sympathetic, and paralyses. The paralysis may be cerebral, spinal, or neural.—*Bulletin of the Cleveland General Hospital.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 5, 1902:

	Cases	Deaths
Measles	614	[illegible]
Diphtheria and croup	357	[illegible]
Scarlet fever	358	[illegible]
Smallpox	75	[illegible]
Varicella	92	
Tuberculosis	262	[illegible]
Typhoid fever	16	[illegible]
Cerebro-spinal meningitis	..	[illegible]

The Candy Habit.—The tobacco, the opium, the tea, the coffee, the alcohol habits are constantly being referred to, but it is seldom that the candy habit is spoken of. It is well known, of course, that a large number of American women consume portentous quantities of sweet meats, that is, unless the fair sex are belied in this respect, but that men also indulge to an exorbitant extent in the toothsome candy, is a fact which has not as yet been widely disseminated. However, when a journal of such unblemished repute for veracity as the New York *Evening Post* stands sponsor for the statement, it e'en must be credited. The journal in question says: "That candy has become the basis of a bad habit—like tea, tobacco, alcohol, or ice-water—has long been admitted by medical men; that its worst victims are not women, however, is not so well known, except to the owners of candy-shops. The fact that one man bought and devoured 400 pounds of the richest chocolates in one summer, and that this gastronomic feat was not looked upon as anything unusual by the candy clerks, will give some idea of the slavery to which the habitual candy-eaters are committed. The man who consumed "confectionery" by the hundred weight is young, and sound in mind and body. He generally yields to temptation immediately after luncheon—although the craving sometimes becomes unendurable at an earlier hour. He estimates that the candy he has bought for personal consumption cost him $250 last summer. He has been an unwilling victim for years, and has frequently "sworn off"—or attempted to. The last time was for three months, and when the self-imposed embargo was raised he bought two pounds of mixed chocolates and ate them between lunch and dinner."

Report of the Ladies' Committee on the Concentration Camps.—The report of the Ladies' Committee on the Concentration Camps in South Africa is, we need scarcely say, very much what might have been anticipated by all level-headed people. Great care was exercised in the selection of the members of the Committee. It was not to be expected that they would find everything perfect everywhere they went, but their report is very satisfactory, nevertheless. There is no doubt that a large amount of sickness, attended with a heavy mortality, occurred in these camps, more especially among the Boer children; but, however much as this may be deplored, it was inevitable under the circumstances. The Boers deserted their families in order to fight against us, and the British authorities in the field out of humanity undertook the care of them rather than allow them to perish on the veldt. The Boers neglect the most elementary principles of hygiene and their notions of treating the diseases of childhood are worse than antiquated. The responsibility and difficulty of undertaking the care of their families were immense under the circumstances. All the stories about the Camp hospitals are simply untrue. It will be curious to see how those who raised a protest against, as they allege, the wholesale murder of women and children will deal with this report of the Ladies' Committee.—*Lancet.*

The Pope's Mode of Life.—Dr. Lapponi, physician to the Pope, gives an account of the routine of the Pope's life. The venerable Pontiff rises at about 9 o'clock, and after celebrating Mass drinks some coffee. From 9.30 to 1 o'clock he receives visitors. He partakes of dinner at 2, which consists of a little soup, a little white meat, a little fruit, and a little claret and water, except on fast days, when fish and green vegetables are substituted for the flesh. After dinner the Pope reads the papers—or, rather, the cuttings made from them for him by his secretary. From 4 till 8 he writes letters and attends to business. At 9 he sups off a bowl of soup and a boiled egg, and at about 11 he retires.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended April 5, 1902:

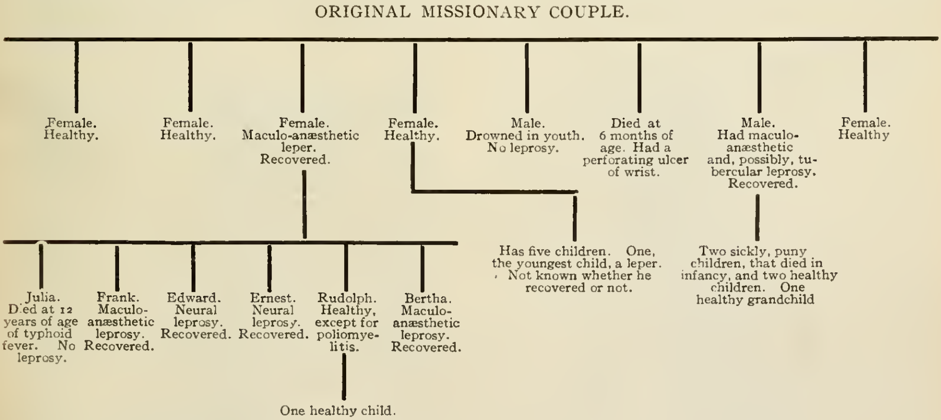
INSTANCES OF SPONTANEOUS CURE IN A LEPER FAMILY.*

By DOUGLASS W. MONTGOMERY, M.D.,
PROFESSOR OF DISEASES OF THE SKIN, UNIVERSITY OF CALIFORNIA

A SHORT time ago leprosy in all its forms was looked upon as an incurable disease, but now a number of writers, such as Hansen,[1] Ehlers,[2] Blaschko,[3] and Hutchinson,[4] regard cure as the natural termination of the anæsthetic form. And even in tubercular leprosy, where slowly advancing but certain death is generally considered to be the almost invariable result, observers are reporting instances of cure.[5]

In support of the view that patients frequently recover from maculo-anæsthetic leprosy, I submit the following interesting family history:

In 1837 a missionary and his wife, both born in New England, settled in the Hawaiian Islands.



ORIGINAL MISSIONARY COUPLE.
Female. Healthy.
Female. Healthy.
Female. Maculo-anæsthetic leper. Recovered.
Female. Healthy.
Male. Drowned in youth. No leprosy.
Died at 6 months of age. Had a perforating ulcer of wrist.
Male. Had maculo-anæsthetic and, possibly, tubercular leprosy. Recovered.
Female. Healthy
Julia. Died at 12 years of age of typhoid fever. No leprosy.
Frank. Maculo-anæsthetic leprosy. Recovered.
Edward. Neural leprosy. Recovered.
Ernest. Neural leprosy. Recovered.
Rudolph. Healthy, except for poliomyelitis.
Bertha. Maculo-anæsthetic leprosy. Recovered.
One healthy child.
Has five children. One, the youngest child, a leper. Not known whether he recovered or not.
Two sickly, puny children, that died in infancy, and two healthy children. One healthy grandchild

The missionary is said to have been a thin man, of nervous, excitable temperament. His peculiarities developed to such an extent that the Missionary Board sent him home, but this did not effect any permanent improvement. At one time in his life, while in Hawaii, sores broke out all over his body. The nature of this disease is not known, but it was called erysipelas. He was an ardent conchologist, and while on a visit to the South Seas died of a fever, caught, it was thought, from a large number of putrifying half-cleaned sea shells kept in the cabin of his small vessel. As it is wished to bring out the markedly neurotic tendency of the family, it may be mentioned that a sister of this missionary was said to have become permanently insane through a disappointment in love.

Nothing is known of any disease tendency in the missionary's wife, or in her family. She bore her husband eight children, and died a short time ago, aged eighty-three years.

The first child of the missionary couple, a female, has always been hypochondriacal, but otherwise has enjoyed good health. Although married, she never bore children. She is yet alive, and is said never to have shown any symptoms of leprosy.

The second child, also a female, taught school, and is said by one of her acquaintances to be an estimable, even-tempered woman; another acquaintance characterizes her as irritable and excitable. She is yet alive, is unmarried, and has never had any children. It does not appear that she ever had leprosy.

The third child, a female, married a German, a native of Hamburg. This German is yet alive, has never had leprosy, nor is there any history of leprosy in his family. This couple had six children. Two weeks after the birth of her third child the mother became insane (erotic mania), and was confined for one year in a lunatic asylum where the discipline was said to be bad. After leaving the asylum the other three children were born. After the birth of the sixth child the mother again became insane, and from then till her death had several attacks of insanity. While on a visit to San Francisco in 1884, she was found to have an erythematous lepride of the face. She hurried back to Honolulu, where she was examined by the Board of Health, who confirmed the diagnosis. The lepride disappeared in a short time, and she died four or five years ago in an insane asylum in Honolulu with no history of her leprosy having returned. The board also at the same time examined her five living children and pronounced two of them (Frank and Ernest) lepers, while the case of a third child (Edward) was declared doubtful.

The fourth child of the original missionary couple, a female, is still alive. When I saw her several years ago she was a tall, thin woman, with deep-set eyes and an intense look. She married a Scotchman, by whom she had five children. Neither she nor her husband, nor any of her children with but one single exception, seem to have shown any symptoms of leprosy. Her one leprous son was under my care for quite a long time suffering from maculo-anæsthetic leprosy of the right palm and of the back. The probable origin of the leprosy in this boy will be discussed when we come to the consideration of the origin of the leprosy of his cousins Frank, Edward, Ernest, and Bertha.

---

*Read before the Alumni Association of the University of California, October 29, 1901.

The fifth child of the original missionary couple was a boy, and was drowned in his youth, no further history.

The sixth child, a twin, died when six months old. Dr. Fitch, to whom I owe a great deal of my information about this family, told me that before death it developed a perforating ulcer of the wrist, that bored clear through the carpus.

The seventh child, a twin, developed leprosy. His case is reported by Dr. J. V. Shoemaker of Philadelphia in the *Medical Bulletin*, March, 1883. As reported by Dr. Shoemaker, this man presented the features of anæsthetic leprosy, such as contraction of the fingers, bullæ, anæsthetic areas, and erythematous patches. There had been a red elevation on the forehead, which had disappeared, leaving an anæsthetic patch. This elevation may, of course, have been a macular lepride. Dr. Shoemaker, however, distinctly describes one tubercle situated in an erythematous anæsthetic area on the back of the left hand, and furthermore says that the man was suffering from tubercular as well as anæsthetic leprosy, and Dr. Geo. L. Fitch also remembers this man as suffering from tubercular leprosy. This man will be referred to again in speaking of the spontaneous cure of leprosy. He is at present living in this country, and, I understand, is, to all appearances, cured of his leprosy without treatment. Neither of his wives, for he has married twice, nor any of his children, of whom he has had four in vinculo matrimonii, developed leprosy. His first wife, whom he married six months after noticing the first symptoms of anæsthetic leprosy, bore him—within a year, a sickly, puny, child that lived but a short time. He later on married again—a widow, who is now dead, and by whom he had three children. The eldest was a sickly, puny, creature, that died at three months of age, the next, a girl, carried off the prize in a baby show, and later married her first cousin Rudolph, a son of the woman previously mentioned as having married a German. She is now about nineteen years of age. I understand that she has recently become the mother of a fine, healthy child.

As to this leper's third child, it is supposed to be healthy, but I have no definite information regarding it.

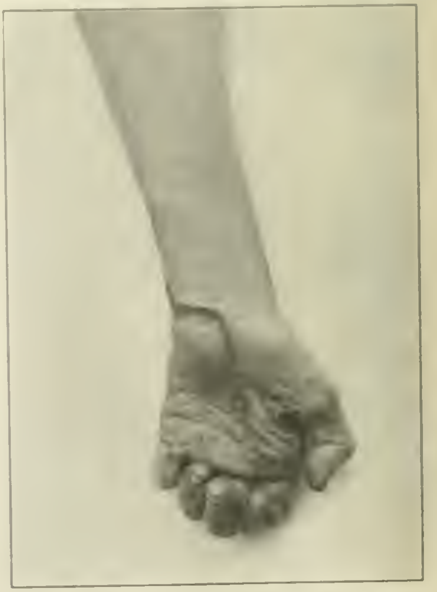
The eighth child of the original missionary couple is still living. She is said to be eccentric, and has remained unmarried. It does not appear that she has ever had leprosy.

We now come to the consideration of the children of the third child of the original missionary couple, some of whom have been casually mentioned as having leprosy. It will be remembered that she married a German, and had by him six children—Julia, Frank, Edward, Ernest, Rudolph, and Bertha.

The eldest of these six children, Julia, died in 1879, of typhoid fever, aged twelve years, and I have no further history of her, other than that she seems never to have had any symptoms of leprosy.

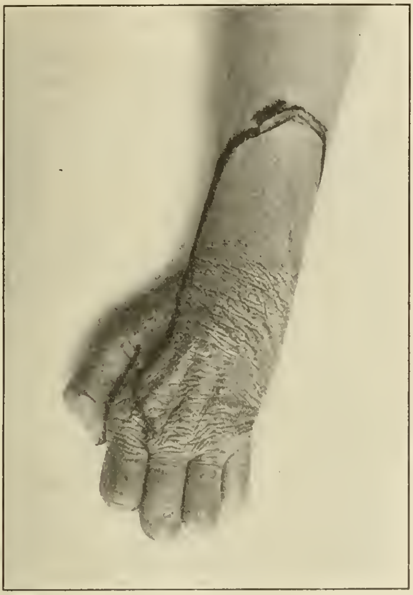
Of Frank, who was in the San Francisco Pest-House, I have a fairly complete history. The reason of this completeness is that he wished to be allowed to leave the hospital, and permitted his examination in order to be regularly discharged. His brother Ernest did not submit to examination before leaving, but as he presented a parallel case to Frank, the Board of Health granted him a regular discharge. Both of them were very sensitive about being examined. My final examination of Frank was made October 29, 1898. He was then twenty-nine years of age. He had come to the United States at the age of fifteen, and had remained in this country up to the time of this examination. He had entered the San Francisco Pest-House, August 12, 1886, twelve years before this examination. He said the disease had first appeared about fifteen or sixteen years before, at thirteen or fourteen years of age, that is, one or two years before being officially declared a leper by the Honolulu Board of Health. He further said that when he was thirteen years of age there was a macular spot on one of his thighs and loss of sensation in the middle finger of the right hand. Two years later macular blotches appeared all over the body, which disappeared in about two or three years. During the first five or six years of the disease the present anæsthesia and the present deformities occurred, and for the past ten years no active symptoms had been observed. The patient denied ever having had any venereal disease, and stated further that he never had been exposed to contagion, as far as Kanaka women were concerned. The symptoms that he showed October 29, 1898 were:

Thickening of the left supraorbital nerve, paralysis of the left orbicularis palpebrarum, and an area of anæsthesia which began as the apex of a wedge near the left side of the nose, and ran outwards, then outwards and upwards, then inwards around the orbit, and ended on the forehead at a vertical line drawn through the supraorbital notch. At the nose, as before mentioned, it began as the sharp apex of a wedge, and gradually broadened until, at its base on the forehead, it was about one inch in breadth.



Frank's left hand. The loss of the sensations of pain, heat and cold in the entire skin to the ulnar side of the black line.

The concave border of this sickle-shaped area of anæsthesia ran near the edge of the orbit below, but gradually departed from it until, on the forehead, it was fully an inch above it. In this anæsthetic area the sensations of pain, heat, and cold were absent, but that of touch was retained. In every other respect the scalp, face and neck were normal.



Frank's left hand. The loss of the sensations of pain, heat and cold in the entire skin to the ulnar side of the black line.

There was a red patch, with slightly irregular borders situated on the right side of the abdomen near the arch of the ribs. This patch was on the same level as the surrounding skin, being neither elevated nor depressed, and the sensations in it were perfectly normal. There was an indication of buff color with the red, and the red color faded on pressure. He said the patch had always been there, and was a birthmark, which was probably correct, The skin of the trunk was beautifully soft and white, perfectly healthy looking, and free from any pigmented or erythematous lepra areas or spots. The patient was well built, both in regard to skeleton and muscles, excepting the atrophy of the muscles of the hands, which will be mentioned further on.

The thenar and the hypothenar eminences and the ulnar borders of both hands were flattened, and all the digits were clawed. He could flex all the digits fairly well, but could extend them only very slightly. The right index and middle fingers had lost their terminal phalanges eleven years before, the patient said. The nails of these fingers were diminutive and misshapen, but all the other finger nails were good. Both the right and left first metacarpal spaces were sunken, and the skin of the back of the hands was deeply wrinkled and thin.

In the right upper extremity there was loss of the sensations of pain, heat, and cold in the entire skin to the distal side of the black line, as shown in the photograph; in the left upper extremity these sensations were lost on the back of the lower part of the forearm, and on the anterior and posterior surfaces of the hand and fingers to the ulnar side of the black line. In these anæsthetic areas the sense of touch was retained, but was dull, and during the examination he was frequently unable to designate the locality where he was touched. He often remarked that a dull instrument was more distinctly felt than a sharp one, which, of course, was owing to the greater number of nerves touched by the broader surface of a blunt instrument.

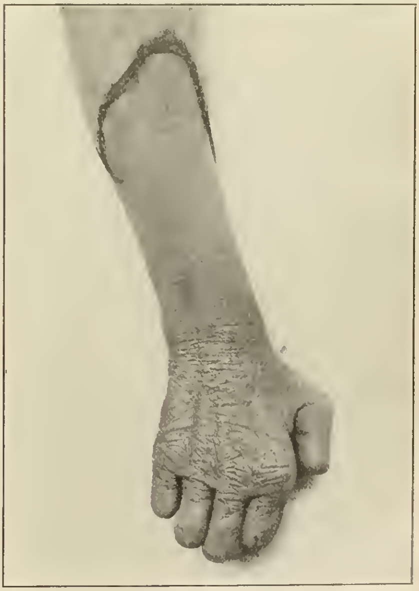
The patient felt that the sensations in the right foot and extending up on the leg for a couple of inches above the ankle were not normal, but they were very little affected, except in the "big toe." The sensations of pain, heat, and cold were wanting in the big toe, but touch with a blunt instrument was felt.

There was loss of the terminal phalanges of the big and the long toes; the other toes were clubbed, and their nails were pegged. The left big toe nail was an irregular mass of horn. The sensations of pain, heat, and cold were absent in the left foot and lower half of the left leg, and over this entire surface he could not feel a sharp point, but he could appreciate a dull one. Because of callosities on the soles of both feet the patient wore two pairs of socks to relieve the pressure. There was a circular patch, about the size of a dollar, on the anterior surface of the lower third of the left thigh, where the sensations of pain, heat, and cold were absent. Touch was felt in this area, and in all other respects the skin appeared to be normal. The patient said he had noticed this patch for the past twelve or thirteen years.

The general intelligence of the patient, as well as his general health, were absolutely unaffected.

The patient's blood was examined for lepra bacilli, but none was found.

The next child, Edward, it will be remembered, was examined, together with his brothers Frank and Ernest, by the Honolulu Board of Health for symptoms of leprosy, and his case was declared doubtful. This was in 1884. He afterwards entered the San Francisco Pest-House, May 12, 1886, with a well-marked maculo-anæsthetic lepride over the left



Frank's right hand. The loss of the sensations of pain, heat and cold in the entire skin to the distal side of the black line.

nesia; persistent paralysis of the left orbicularis palpebrarum muscle; ectropion of the left lower lid; and a hard knotted cord about the size of a whip-cord running down the left side of his neck. Dr. Geo. L. Fitch injected ichthyol into the anæsthetic patch on the cheek, and it suppurated, leaving a deep scar. This boy soon grew tired of the lazy, eventless life of the pest-house and ran away. He has had no symptoms of his disease since 1887 or 1888 and is remarkably robust, industrious and of good intelligence. He constantly dreads a return of the disease and takes strychnia and creolin, thinking to ward off a possible attack. He has been twice at Kusatsu Springs in Japan, with of course no result, as there were no active symptoms of leprosy to control.

Ernest entered the San Francisco Pest-House, August 28, 1886, at fifteen years of age. He was born in Hawaii and said he first noticed the disease, as an anæsthetic patch, on the dorsum of the right foot near the toes in 1884, when thirteen years of age. In 1888 Dr. Geo. F. Shiels and Dr. J. H. Barbat removed about one inch of the left radial nerve, which I examined for lepra bacilli, but found none. I only found a decrease in the number of nerve fibers, and an increase in the connective tissue, with the formation of cicatricial tissue. When I took his history in 1893 both hands were clawed, and were typical shrivelled leper hands. The skin of the hands, except for loss of sensation, was normal. There was no shortening of the phalanges, and the nails were in good condition. The loss of sensation on the right upper extremity was irregular, for instance, sensation was normal on the back of the right thumb, but loss of sensation extended up as high as the junction of the middle with the upper third of the upper arm; unfortunately, my notes do not state the limits of the loss of sensation in the left upper extremity. Some of the joints of the fingers had been injured, and the synovia had run out. The thenar and hypothenar eminences of the ulnar side of both hands were flattened. He could not abduct either little finger, and the pucker caused by the action of the palmaris brevis muscle was absent from both hands. Both first metacarpal spaces were decidedly sunken. The others were not so much so. The epitrochlear lymphatic nodules in each arm were enlarged. Both radial arteries were thickened, but not hard. Both ulnar nerves were thickened and irregular as they ran along the epitrochlear groove. His condition never changed during all the time I observed him, and I had frequently seen him during a number of years—at least five—previous to 1893. In all other respects he enjoyed good health.

Rudolph, the fifth child of the third child of the original missionary couple, now lives in Hawaii, and is married to his full cousin, the daughter of the leper examined by Dr. Shoemaker. Dr. Fitch says that Rudolph had an attack of poliomyelitis at two years of age, which left a deformity of his right lower extremity. He has, however, never shown any symptoms of leprosy.

Bertha, the sixth child of the third child of the original missionary couple, was pronounced a leper, September, 1884, when about twelve years of age, by Dr. Geo. L. Fitch, on account of a copper-colored, anæsthetic ringed patch on the right side of the face. She recovered without any deformity, and still lives in Hawaii, and occupies a responsible position, where she earns a fair salary.

In regard to the cures: Of the seven leprous descendants of the missionary couple five are still alive and have recovered. Of the other two, one, the third daughter, who died in a lunatic asylum, it will be remembered, was pronounced a leper by a doctor in San Francisco, which diagnosis was confirmed by the Honolulu Board of Health in 1884. The erythematous lepride from which she suffered, it is said, disappeared in about one year, leaving no trace, and she died four or five years ago in a lunatic asylum, showing no return of the disease. Granting these facts to be true, she remained free of leprosy for about ten or eleven years. Unfortunately, exact dates could not be obtained. The other of these two, the grandchild of the original missionary couple by the fourth daughter, whom I reported before the American Dermatological Association in 1899 as having an erythematous lepride of the palm, has been lost sight of for some years, and therefore I cannot say how his malady is progressing.

Of the five descendants who are still alive and have recovered, four—the four grandchildren by the third daughter—have long since passed the probationary ten years without active symptoms, and I have good reason to believe the seventh son, whom it will be remembered was examined as a leper by Drs. Fitch and Shoemaker, has been equally fortunate, although he is said to have had tubercular leprosy. It, however, must be said that a perfectly honest doubt could be entertained of his disease being of the tubercular type at all. This does not reflect on the diagnostic ability of either Dr. Shoemaker or Dr. Fitch, who has had great experience in leprosy. A short time ago, for instance, there was a maculo-anæsthetic leper in the University of California Clinic, who showed in the center of some of the diseased patches an infiltration so marked as to constitute a tubercle. These were not the tubercles of tubercular leprosy, however, for on staining some of the juice squeezed from the infiltrations no lepra bacilli were found, while if they had been the tubercles of tubercular leprosy, bacilli would have been found in large numbers. Years ago, when Drs. Fitch and Shoemaker examined their patient, this differential point was not available.

For a long time I looked upon this family as furnishing an excellent example of heredity in leprosy, and one can easily see why. I first became acquainted with the three grandchildren of the original missionary couple, who were in the San Francisco Pest-House. Afterwards I learned that a sister of these three grandchildren had been found a leper, and that their mother had also had leprosy. Some time subsequently I became aware of the fact that one brother of the mother of the four leper children had been found a leper of the neural and tubercular type, and that another brother had had a perforating ulcer of the wrist. It was while these facts were fresh in my mind that a strong hearty boy of fourteen years of age was sent to me from one of the interior towns as a leper suspect. I was easily able to confirm this suspicion as correct, and shortly afterwards was astonished to find he was a full cousin of the three inmates of the San Francisco Pest-House, and a grandchild of the original missionary couple. At this stage I naturally drew the conclusion that the facts, as a whole, made a strong case of heredity in leprosy. It was while I was of this mind that the structure I had so laboriously built up was shaken. While conversing with the late Dr. J. K. Smith of Honolulu about the family, he told me that the two families of the grandchildren of the original missionary couple, both those by the daughter who had married the German and those of the daughter who had married the Scotchman, used to play with some Kanaka children who lived in a cottage close by, and who were obviously afflicted with leprosy.

In going over the facts as they now stand it must be said that the probability of heredity in transmitting the disease becomes more and more remote. There is no evidence that the original missionary couple suffered from leprosy, except that one child had had perforating ulcer of the wrist. Of their children the third and seventh were undoubtedly lepers, but they both had abundant opportunity of acquiring it, the one by detention in a badly-regulated insane asylum in Honolulu, while suffering from erotic insanity, and the other through his unrestrained life among the Hawaiian natives. This son had two puny, sickly children that died in infancy, but it is just as probable that they died of syphilis as of leprosy.

For a long time I considered the hereditary nature of the disease where four of the children were affected as being particularly well established. I thought the mother might have caught the affection in the lunatic asylum, and might have transmitted it subsequently to her children. A defect in this reasoning lay in the fact that the mother did not show symptoms of leprosy till long after the birth of all her children. In fact, her leprosy was found at the same time as that of her children, in 1884, and may have been acquired from the same source; or her children may have acquired leprosy from the above-mentioned Kanaka children, and have transmitted it to their mother. Another fact strongly against heredity was the robust health of the children. If the children had been affected by leprosy *ab ovo*, one would imagine their general health ought to suffer.

The failure of the disease to cause deterioration of the general health is, indeed, in itself an interesting feature, considering at what an early age, in many of these instances, the disease must have been acquired. It seems likely that the four leper children of the third daughter, and the one leper child of the fourth daughter of the original missionary couple, all acquired their leprosy at the same time. If so they must have contracted the disease before the sixteenth, fifteenth, thirteenth, eleventh, and fifth years of age respectively, as these are the estimated ages of Frank, Edward, Ernest, Bertha, and their cousin Claud in 1884.

Another matter of interest is the fact that two of them remained so long in the San Francisco Pest-House and did not acquire the disease again from the other lepers there. These two entered the pest-house in May, 1886, and remained until October, 1898—over twelve years. During that time they were constantly in the company of lepers. I suppose that there was an average of fifteen lepers in the pest-house all that time, many of whom were in the last stages of the disease. The hygienic conditions were of the worst. During the wet, cold weather in the winter they all used to huddle together in a small, dirty room, which was overheated and badly ventilated. Here they all played cards and gossiped throughout the long, weary, lazy days. One would think it a particularly favorable place to catch the disease, yet not alone did these patients not reacquire the disease there, but not one of the patients who were not lepers, nor the nurses or superintendents of the institution, who mingled freely with the lepers, have ever been known to acquire the disease in the San Francisco Pest-House. This failure to transmit the disease in lazarettos is not peculiar to the San Francisco Pest-House, but has been frequently noticed in other institutions where lepers are confined. It seems to show that some unknown conditions must be favorable or the disease cannot be transferred, and therefore no inferences as to the personal immunity of the individuals not attacked can be deduced.

I long thought that the neurotic tendency of the family, so well shown in the preceding history, had a determining influence in the predominence of the neural type of leprosy in its members. This also will not stand before criticism, for the tendency of leprosy to attack the nerves is so marked that one always expects to find implication of the nerves in either macular or tubercular leprosy. Therefore the striking feature of this family is not the implication of the nerves which is common to all lepers, but in their comparative freedom from tubercular leprosy, there being but one of them with the tubercular type, and even he possibly, as above explained, may have had the maculo-anæsthetic type with marked central infiltration.

Of the two forms of the disease, macular and tubercular, the macular form is generally conceded to be the milder. Why this family was attacked by the milder form of the disease so predominantly, and why it ran such a particularly mild course, is not known. Armauer Hansen states that climate has a modifying influence; that in the low, damp bays in Norway, the tubercular or severer form of leprosy prevails, while on the high, dry promontories the maculo-anæsthetic variety predominates. Hawaii has a climate that is moist, hot and debilitating, while the part of California to which five of the afflicted members of this family afterwards moved is dry, temperate and bracing, and is therefore inferentially favorable to the cure of leprosy. It must be said, however, that both of the lepers of this family who remained in Hawaii had the disease in the mild maculo-anæsthetic form, and in both the symptoms disappeared in a very short time. The influence of climate in modifying any disease can only be determined by statistics, but incidentally I may remark that two of the worst instances of tubercular leprosy I have ever seen not alone ran their course on this Coast, but acquired their disease here.

4. "On Cases of Recovery from Leprosy." "Lèpra," Vol. II., Fasc. 2, fol. 53.

5. For example, two such cases have been reported in *La Lèpre* en Crète par les drs. Ehlers (Copenhague) et Cahnheim (Dresde), "Lèpra," Vol II., Fasc. 3, fol. 151. Geo. Thinn has recently reported two cases where patients recovered from nerve leprosy, but he attributed the cures to the drugs used.—*British Medical Journal*, May 4, 1901.

Compensatory Functional Hypertrophy between the Parotid Gland and the Pancreas.—F. E. Italia describes a number of experiments conducted on animals with a view to ascertaining whether there is any compensatory functional hypertrophy between the parotid and the pancreatic glands. These experiments consisted in the production of atrophy or necrosis of the pancreas, its injection with tubercle bacilli, and enucleation of the parotid. Hypertrophy of the uninjured gland followed in each case, with cellular neoformation and increased secretion. The cause for this is found in the medulla oblongata, in which are situated the reflex secretory centers of both parotid and pancreatic glands. If one center is rendered inactive through the impaired powers of one of the glands, the other attempts to compensate by hyperactivity, and the gland is forced to secrete more abundantly. The cells of the gland require more nourishment in consequence of their increased activity, and this more abundant nourishment is the chief factor in the neoformation of cells.—*Il Policlinico.*

A CONTRIBUTION TO THE STUDY OF PERITONSILLAR ABSCESS.

By DONALD M. BARSTOW, M.D.,
NEW YORK.

ASSISTANT SURGEON IN THE THROAT AND EAR DEPARTMENT OF THE NEW AMSTERDAM EYE AND EAR HOSPITAL.

The tonsils are described by Hodenpyl[1] as "Two in number, situated upon either side of the mouth, between the anterior and posterior pillars of the fauces. . . . Their long axis, when the mouth is widely opened, is nearly vertical, with the mouth shut nearly horizontal. They are separated from the internal carotid artery by the superior constrictor muscle. . . . In structure the tonsils consist of an aggregation of lymph nodules, bound together by very fine but extremely tough fibrous connective tissue. The nodules are arranged about a series of depressions, from eight to fifteen in number, known as crypts. These crypts are lined with epithelium, and they secrete a viscid mucus, containing a few leucocytes."

The tonsils first appear in the fourth month of intra-uterine life, as a bunch of round cells, lying in a furrow between the palato-glossal and palato-pharyngeal arches of the embryo (Paterson[2]). This furrow is, in early fœtal life, continuous with what later becomes the fossa of Rosenmuller. The soft palate, starting as a bud on the posterior surface of the superior maxilla, grows backward, joining itself to the palato-glossal and palato-pharyngeal arches, which thus form the pillars of the fauces. Between these the tonsils appear. They are fully formed at birth.

The fully-formed tonsil does not completely fill the interval between the pillars. There remains a space which was first described by His in 1885, and named by him the supratonsillar recess. This recess varies in shape and size, is usually situated in front of and above the tonsil, and may extend for a varying distance outward and downward toward the alveolar process of the superior maxilla, or upward and inward toward the median raphe of the soft palate. It is lined partly with mucous membrane, continuous with that of the mouth, and partly with irregular patches of lymphoid tissue, these representing supplementary tonsils. The opening of the recess is above the tonsil, and points inward. It is bounded above and outside by the soft palate, posteriorly by the posterior faucial pillar and by the tonsil, and anteriorly by the anterior pillar, and a projection from it, which is called by His the "plica triangularis."

The plica triangularis is a thin fold of mucous membrane growing forward and inward from the anterior pillar. It hangs in front of the tonsil, to which it is usually more or less adherent. Its form and extent vary considerably. In children it usually covers the anterior aspect of the tonsil, giving a smooth and shining appearance. In adult life, as the tonsils atrophy, it gradually folds backward over the shrinking gland.

The upper zone of the tonsil is in direct relation with the supratonsillar recess, and the upper crypts empty into it. The tonsillar structure, at this point, is much looser and more open than elsewhere. The crypts, three or more in number, are wide and deep, and sometimes communicate beneath the surface with each other or with those in the central zone of the gland. The greater the development of the upper part of the tonsil, the smaller the opening of the recess, and correspondingly the better chance of its becoming a closed cavity.

The functions of the tonsils cannot be stated with any certainty. Many suggestions have been made by different writers. Labbé[3] thinks that they take part in the formation of blood by transforming lymphocytes into mononuclear leucocytes. Masini[4] reports some experiments which seem to have convinced him that the tonsils have an internal secretion, analogous to that of the suprarenal bodies. The conclusion seems to be based upon insufficient evidence. Philipp Sterck[5] describes a flow of leucocytes from the follicles through gaps between the epithelial cells, and suggests that the tonsil is the chief source of salivary corpuscles. Packard[6] says that, as the tonsil is found only among the higher animals, we may exclude the idea that it is a relic of evolution. He regards it as of the nature of a lymph-node, and maintains that we should assign to it a function similar to that of lymphoid tissue in other parts of the body, namely, protection of the body against invading germs, by filtration, attenuation, and delay, as a skirmish line holds the enemy in check, while the main army prepares for defence.

This view of Packard appears reasonable. It seems fairly certain that the so-called "Ring of Waldeyer" has a function, and its position, at the double gateway of the digestive and respiratory tracts, is the one that nature would most probably choose for a military outpost. Furthermore, experiments by many observers—Pirera,[7] Hodenpyl, and others, seem to show that while foreign matter may, under certain conditions, be absorbed into the tissue of the gland, living germs cannot pass through the tonsillar substance to enter the general circulation.

The bearing of this fact, if fact it be, upon the pathology and treatment of inflammatory and suppurative conditions in and around the tonsils, is very important. If we grant to the tonsils a conservative action, we are bound to hesitate before urging their complete removal. Yet, on the other hand, we are no less bound to give to our patients such relief as surgery may afford from the discomfort and danger which diseased tonsils inflict.

Probably the most distressing disease of the tonsils in adult life is recurrent peritonsillar abscess, or so-called "quinsy." This disease is common and obstinate, and often the recurrences are so frequent that a patient may be incapacitated from work during several months in every year. And it may well be doubted if there be any clinical picture known to medical science which is more painful and distressing than that of a patient with an active quinsy. It seems to the writer that the true nature of this disease is imperfectly understood. The real trouble appears to lie in the supratonsillar recess, and not, strictly speaking, in the tonsil itself.

Let us view the history of a typical case. The tonsil is contracted and partly atrophied. The upper zone is in close contact with the roof of the soft palate, and a cotton-wrapped probe, bent at a right angle, can be introduced for about half an inch into the supratonsillar recess, and withdrawn, covered with cheesy, foul-smelling material. This is the condition usually found between attacks. Now, let some irritant be introduced, living or non-living, from outside or inside the body, and inflammation follows in the shrunken tonsil. As a result, we have congestion and slight swelling of the entire gland. The upper zone, being, as said above, looser in structure than the rest, swells more extensively, and thus shuts the only opening of the supratonsillar recess, making it a closed cavity. Then the bacteria, which live there, go actively to work, and we have the resultant abscess, which points, in 90 per cent. of all cases (Coakley[8]), through the anterior pillar, or, in other words, over the most common site of the supratonsillar recess.

Commonly, after the attack is over, some effort is made to remove the tonsil. These efforts are usually ineffective as regards the prevention of a recurrence.

The writer wishes to draw attention to a plan of treatment used by him in ten of these cases during the past two years, which has given good results thus far, although the list of cases is a short one, and several of the patients treated have drifted out of sight. All the patients had had at least two attacks of peritonsillar abscess, and one of them had had no less than eight. The results are as follows: Two of the patients have had complete immunity for two years, one for a year, one for six months, one failed absolutely—the operation was incomplete—and five drifted out of sight too soon to afford any opportunity to judge of results.

The object of the treatment is, briefly, to open up the supratonsillar recess so widely that it will drain itself freely, repair its diseased mucous membrane, and cease to be a catch-all for germs and débris. This result is accomplished as follows: A 4 per cent. solution of cocaine is injected from a hypodermic syringe into the body of the tonsil and into the peritonsillar region, through several points in the anterior pillar. This gives a degree of anæsthesia quite sufficient for the operation. Then, with a bistoury, a curved incision is made from above downward, dividing the plica triangularis at its base from the anterior pillar. Next, with a Myles' tonsil punch, the entire upper part of the tonsil is removed piecemeal, together with a part or the whole of the plica triangularis. If the instrument be sharp and in good order, the operation is entirely painless. A dull instrument, however, pulls like a dull pair of barber's scissors, and this is exquisitely painful. The earlier part of the operation is quite easy. Toward the end, however, it becomes necessary to burrow quite deeply between the pillars, and there is danger, on the one hand, of failure to accomplish the desired end; on the other hand, of wounding one of the pillars and causing hemorrhage. If, however, the tongue be smartly depressed, the patient, in gagging, turns the stump of the tonsil forward toward the operator, and the operation can be finished, step by step, under his eye.

When neatly and carefully done, the operation is quite painless, and the resulting sore throat very trifling. It is not always possible to avoid wounding the pillars of the fauces, and when this happens there is always soreness, and there may be hemorhage. Dr. R. C. Myles has shown that hemorrhage after tonsillotomy is very rare, except when the pillars are wounded, for the tonsillar arteries are small, terminal twigs, and there is no vessel which passes through the tonsil to supply other structures.

Only very rarely, and with an unusually restless patient, is it necessary to divide the operation into two sittings. The usual time consumed is less than fifteen minutes, and most patients bear the strain without much trouble. Should it, however, be necessary to remove both tonsils, it is better not to attempt both on the same day.

21 West Fifty-third Street.

MIND AND BODY.

By J. Allen Gilbert, Ph.D., M.D.,

Portland, Ore.

The methods and promises of psychiatry and experimental psychology in general have led many into the misconception that everything that is of worth in man is to be found in the physical organism, and that all phenomena can be explained on the basis of physiology and physics. Men so little advanced in the knowledge of psychology and physiology that they still speak of the "*five* special senses" of man, thrust upon us the tenet that "mind is not an entity, but an exhibition of force resulting from the collective functions of grey nerve tissue, not only of the brain but of the entire nervous system."

In a former article I have entered an appeal for the entity of mind, however strange it may seem that such an appeal should be necessary. The aim of the present article will be to call attention to the nature of the external world in its relation to the psychic aspect of man.

Things are not ready-made objects, which are recognized by being stamped upon the mind in some inexplicable way, but only through conscious activity, *i. e.* by a process of sensation, perception, apperception, etc., are ontological entities transformed into the cosmological realities, which we conceive and describe in terms of space and time. Neither is mind to be looked upon as a sort of thing independent of and separated from all other reality, carrying on an existence exclusive and self-sufficient, any more than things which are dependent upon consciousness for their existence *as things*, *i. e.* as objects in space, and having all those qualities, such as length, breadth, weight, color, etc., which can only be furnished from consciousness. The fact that things derive their existence *as things* from consciousness does not in the least detract from their reality and existence, but only adds the qualities and attributes which make of them objects to be dealt with in terms of physics. Men justly demand the tangible and perceptible. Why? Because in that form alone can realities be manipulated and experimented upon, and because we are limited by certain categories of thought which bind us to the spatial and temporal. Space is but a means by which consciousness delineates reality. We think in terms of space because space is a method or mode of mind's activity, but space no more belongs to the thing as such than pain belongs to the amputated limb, although located there by the patient. We say that dimension belongs to things as such, and yet when the conscious process is analyzed by which we build our sense experiences into objects it is found that space is but a necessary mode of mind's activity in dealing with that which is other than self. By a process of eccentric projection we posit in space objective things, many elements of which are supplied by consciousness. This conception does not reduce things to subjective realities, but only helps us in understanding that by the action of the "other than me" upon me, I react to it and clothe this "other than me" in physical qualities derived from my own activity—consciousness.

If there is anything real to man it is pain, and yet have we in any way detracted from the reality of the pain by dirempting it from the body or nervous system, or have we in any way curtailed the possibilities of the body or nervous system when we declare them incapable of pain as *things?* Such a conception gives both mind and things—to the latter of which the body belongs—a reality referable to a unitary basis which science calls nature. It does away with that dreaded antagonism between so-called matter and mind. Things stripped of their spatial elements added by consciousness fall back into one reality where mind and matter mingle with an intimacy which defies analysis. To be sure, to take away these activities of the thing which cause us to respond in terms of length, breadth, color, weight, etc., would be to take away the thing itself, but in order that these activities may be interpreted or built up into the said qualities and attributes, consciousness is absolutely indispensable. This conception thus resolves mind and matter into an action and interaction of entities, which go to make up one great throbbing reality which different scientists have seen fit to designate by different names. To explain the relation of mind and body is, then, the same problem as to explain our relation to each other, or to explain the relation of things one to the other. Ontologically, it is inexplicable. To explain in terms of physics is simply to explain that which is physical, *i. e.* the qualities with which things are invested or the visible and tangible manifestations which express themselves chronologically before us. Explanation, therefore, cannot dip down into ontology, but must of necessity be confined to the cosmological aspect of reality.

That the relation I hold to my body is more intimate than my relation to other bodies or things goes without saying, but the fact (?) that my consciousness changes synchronously with the changes in my nervous system is no proof that I am a result or product of nervous matter. The application of the law of causation to this relation would, in consistency, demand that the same order of events be universally maintained, but the opposite is, at least, tacitly admitted by all, viz., the effect of mind on body as well as the effect of body on mind. The fact is we start with consciousness, and we are conscious by and through our experience with that which is other than ourselves. Among those entities which are "other than me" is to be found that complex and delicate organism, my body, to which I maintain a peculiarly intimate relation. Yet, here the line is hard to draw, for one's personality is so thoroughly permeated by that which is personal possession that we often conceive ourselves to be not only what we are, but what we are plus that which we have, giving us, according to Professor James' conception, a number of selves differing according to the aspect from which they are viewed. Thus a man's self increases and decreases, in a sense, in proportion to the extent of his influence and breadth of comprehension. The broad-minded man is given precedence not by the size of his mind, so to speak, but by the scope of facts which go to make up his consciousness, or by the variety of things he is able to take up within himself and make a part of himself. Just so, in dealing with objects which are classified as inanimate. Before we can know them we must in some sense take them up into ourselves and vivify them with our own existence, as it were. This is the process of all communication between fellowmen and things. For example, when I say "sun shines" there is not some sort of an idea already whittled out and shaped ready for absorption by some other mind. On the contrary, the mind realizing that sentence-conception must live over that which has been experienced in saying "sun shines." However rapidly the process of forming the sentence and the conception involved therein may be consummated, the process is still there, and the words have been taken up in consciousness and given a meaning which, by the similarity of activity of minds and nervous systems, has resulted in a mutual understanding. The thought must not be lost sight of, however, that each person builds up his own conception of what is passing. How else can mistakes occur? Mistakes and misunderstandings are the result of the difference in the personal equations of the individuals concerned. In knowing any object we stamp upon it our own personality. We "mind" it, as it were, with our own conscious activity, adding to it elements of our own conscious life.

Is the step a long one when we try to explain all objects or things on the same basis as we have explained the verbal expression "sun shines?" This has depended upon hearing. Let us carry it for a moment over into sight. That which is "other than me" has acted upon me and I react by seeing, as we say, the visible object "desk" instead of hearing the clause "sun shines." Just as we synthetically put together "sun" and "shines," each of which was primarily built up from simpler elements, and from them draw the concept of the process of light shining, just so we synthetically join together the impression pigeon-hole drawer, top, color, etc., all of which were primarily built up from simpler elements and draw out of them the concept "desk." Experiment in psychology is but little more than an attempt to analyze that complex process by which we build up our percepts and concepts into more far-reaching generalities. Before we can have any concept corresponding to "desk" we must, from its activity upon us through our various senses, build up that entity which is commonly designated a desk. In that sense it has not derived its reality from me any more than I mine from it, for at the time being we are both, *i. e.* "desk" and "I," dependent the one upon the other for our existence, inasmuch as the existence of each is but its activity at the time. Just so all nature is one great acting and reacting reality, in which individual units gain themselves only by manifesting themselves according to their individual natures. Mind and body must be looked upon as such individual units. Thus each thing is what it is in virtue of its own activity, and my conception of what it is is the resultant of my activity upon it and its reaction upon me, or *vice versa*. We, as persons, act and react in terms of consciousness, and to us things only have meaning in terms of consciousness. To prove that that which is "other than me" also reacts in terms of consciousness would be difficult, if not impossible, but leaves us at least with the conviction that the "other than me" in some way carries on an existence comparable to our own.

In the final analysis, to explain the relation of mind and body is the same problem as to explain the relation of one mind or thing to another. We judge mind by its manifestations through the physical organism, and it is futile to hope to explain how one causes the other, or even how one is related to the other. We can do nothing more than note, compare, and make deductions from the data derivable from each. All explanation begins and ends in the unexplained. Because the relation between mind and body cannot be thoroughly explained, physicists, neurologists, and physiologists attempt to surmount the obstacle by making mind a product of nerve tissue, but in spite of themselves, they at times refer to the effect of mind upon body even though they have denied the entity of the former. To be unable to explain thoroughly the relation of mind and body is no disgrace, for it is, as stated above, the same problem as to explain the relation of any two objects or any two persons, or any object and person. The fact that there is relation, *i. e.* action and reaction, between body and mind brings both within the realm of the same sort of activity, and inasmuch as man has within himself elements which stamp him as moral, one cannot help carrying similar elements over into that which is "other than me," even though absolute proof may be wanting.

ON THE PENETRATION OF THE HUMAN BODY BY ORDINARY ACTINIC LIGHT.

By WILLIAM S. GOTTHEIL, M.D., and MILTON W. FRANKLIN, M.D.

In the present state of our knowledge concerning light, the following assertions may be made:

1. That the tissues of the human body, like all other substances, are penetrable to varying degrees by the wave vibrations of light; and that these vibrations form an essential part of the stimuli that determine the life activity of the cells, with effects that may be beneficial or injurious.

2. That the light vibrations affect bacterial life, and are, in general, injurious or fatal to it.

3. That of the various components of ordinary white light, the rays in the more refrangible end of the spectrum, the blue, violet, and ultra-violet have far greater chemotaxic and actinic effect than those of the red end.

4. That these so-called actinic rays are comparatively more abundant in the electric arc than in sunlight.

5. That the action of light upon the tissues depends upon the rays absorbed, not upon those transmitted; but that when several superimposed layers are to be acted upon, the effect upon the deeper ones depends upon the actinic transparency of the superficial strata.

The two opposite properties of actinic transmission and actinic absorption, or transparency and opacity to the light waves, are possessed in varying degrees by all the tissues. The ordinary phenomena of transillumination show the perviousness of thin layers, as in the ear or cheek, to the visual rays; and Gadneff's and Soluchat's well-known experiments, in which sensitive silver salts, in sealed capillary tubes, introduced under the skin and into the tissues, and then exposed to sun and electric light, with reduction, show actinic penetration. Freund has recently made exact spectroscopic determinations, showing that chemically active, as well as visual rays, pass freely through epidermic tissues of considerable thickness.

That actinic absorption occurs in the tissues is evident from the fact that the body is opaque, both optically and chemically, to light under ordinary circumstances. In estimating the value of any special source of light for the purpose of influencing the deeper tissues of the body, it is necessary to prove the efficient penetration only of the actinic or chemical rays; for the portion reflected from the surface is small, and all the rest, save that which passes through the tissues, is absorbed and effective. The question is an important one, for on its answer depends the entire applicability of the method for treating affections of the internal organs.

For the purpose of determining it, a series of experiments were made, the results of which are here given. The source of light was an electric arc in the condensation apparatus or actinolyte, operated at sixty amperes, and with condensers of an angular aperture of sixty-seven degrees. The rays were arranged nearly parallel in a pencil, being just sufficiently convergent to form a circle large enough to cover the plate employed.

Ordinary photographic plates were used as sensitometers, since they react more especially to the actinic or chemical rays of the violet end of the spectrum, which are the very ones which we desire to employ therapeutically. The subject of the experiments was a mechanic, aged twenty-three years, with good, firm tissues.

Developed negatives of average density were selected, and to the face of each the film side of a sensitive plate was applied. The edges of the plates were bound with black lantern slide strips, and the back of each set covered with thick opaque paper. By this means the plates were so protected that light could reach them only through the negative.

The prepared sets of plates were applied, with the negative next to the skin of the body of the subject in the dark room, and the whole covered with adhesive strips and black cloth so thoroughly that no light could possibly affect the plate without first passing through the body. When all was ready the subject was seated in front of the arc and the light passed through various portions of his body on to the sensitive plates.

The time employed for each exposure was determined by experiment, since there were no data available for the purpose; and even if there had been the differences in the densities and thickness of the tissues in different individuals would prevent their being of much use. Several series of similar experiments were made, to prevent error. The subjoined, with the result attained, will serve as an example:

Plate 1.—Light on the anterior surface of the forearm, plate on the back. Thickness of transillumined tissues, 8 cm. Time of exposure, ten minutes. The plate shows the image of the negative, together with the shadows of the radius and ulna.

Plate 2.—Taken through the shoulder. Light upon the anterior upper portion of the thorax, plate upon the scapula. Thickness of tissue about 16 cm. Time of exposure, twenty minutes. This plate showed a fairly even deposit, save where the great differences of density of the various parts of the scapula affect the result.

Plate 3.—Taken through the left abdominal region. Light upon the left umbilical region, plate on the left lumbar. Depth of tissue, about 19 cm. Time, thirty minutes. This plate showed a very even and perfect exposure, save where the disc of light, not quite accurately directed, failed to cover the entire plate.

Necessarily the amount of actinic light transmitted through tissues of such thickness and varying consistency is relatively small; in addition to which the red color of the blood further hinders its passage. If the contrary were the case, and the tissues were very transparent to the light, but little effect could be expected; for it is the absorbed light that is changed into other forms of energy, and is efficacious. Hence, therefore, the exposures were prolonged.

The problem before us was to ascertain if, with the most powerful means of artificial light at our disposal, the actinic vibration could be made to traverse two layers of skin, and the varying thicknesses of subcutaneous fat, muscle, bone, and organs, the whole permeated in every part with a moving red fluid, to such an extent that the portion of it passing through would affect a sensitized plate. This has been abundantly proved for thinner layers, but not, so far as we can ascertain, for the entire thickness of the body. Yet a light must be able to do this, if the organs of the interior of the body are to be influenced by it.

Conclusions.—1. Light, in proper concentration from a source of sufficient actinic power, can be made to penetrate the entire thickness of the human body, including both surfaces of the abdomen, all the internal organs are accessible to its influence.

2. Since in portions of the trunk of the body, however, not more than half the thickness of the trunk from a superficial surface need be traversed to reach each organ, much shorter time is required for effective actinic penetration to any depth, is only a fraction of that employed in the experiments, and, conversely, if the time employed is equal, the chemotaxic effect will be far greater.

3. The proof of the penetration of actinic light to and through the internal organs apparently opens a field for its successful employment as a therapeutic agent in internal maladies, in view of its admitted efficiency in a number of external affections.

SUPRAPUBIC CYSTOSCOPY.

BY DONALD KENNEDY, M.D.,

[illegible]

In reporting this case of suprapubic cystoscopy, which is, as far as I have been able to learn, the first ever made, I shall touch on the cases which led up to this procedure, in order to give credit to the man whose work suggested the feasibility of it. In 1894 Wishard of Indianapolis proposed to relieve prostatic retention in the following manner: A medium-sized trocar canula is selected, and with it the bladder is punctured above the pubes; the trocar is then withdrawn and a catheter introduced through the canula, which is then withdrawn, leaving the catheter *in situ*. When the congestion of the prostate has subsided, and the urine is passed by the urethra, the catheter is removed from the suprapubic wound, which readily heals. This method appealed to me as a rational one, and, knowing the ability of the author, I determined to try it. I followed his technique in two cases, and the results were ideal. It then occurred to me that if at the time of puncture I could get a view of intravesical conditions, I might gather information which would aid me in the selection of an operation. By it I hoped to be able to determine the size and contour of the prostatic lobes; the general condition of the bladder walls, and also to determine, as sometimes occurs, if there might be a stone in the postprostatic pouch. With this end in view, I had a trocar made to fit a No. 21 Otis Endoscope, and proposed to use this instrument, to which I could attach the light, instead of the ordinary trocar-canula. On July 16, 1901, I was called to see M. J., laborer, sixty-seven years old. He had been suffering from prostatic hypertrophy for several years, and for the past eighteen months had depended upon the catheter to empty his bladder. On arising he attempted to pass the catheter as he had been accustomed to do, but found it impossible. I attempted to pass a Mercier coudé and bicoudé instrument, but failed. The bladder was then tapped with the trocar-endoscope and about nine ounces of urine withdrawn; the tube was plugged and a tape passed around the body over the disc of the tube to hold it in place. In three hours the plug was removed and three ounces of urine withdrawn; this was repeated every two hours until the bladder was empty. The few drams of urine remaining were "sucked up" by means of a bulb attached to a catheter. The bladder being empty, I attached the lamp to the tube and attempted to get a view of the interior of the viscus. My anticipations were only partially realized. The general condition of the bladder was plainly visible; areas of greater or less inflammation were readily made out, the mouths of the ureters were easily detected, and had stone been present in the postprostatic pouch it would have been revealed. I was not able to learn as much of the size and contour of the prostatic lobes as I had hoped. The failure I take it was due to the fact that with reflected light the distal end of the tube had to be almost in contact with the bladder wall in order to illuminate it, thus giving a very limited area under observation. In order to determine the size of the lobes it will be necessary to have under observation a larger area than I was able to obtain with this tube. Experiments are now being made by the writer to determine what sized tubes can be used with safety. At the suggestion of Dr. Valentine, I shall use one of his short urethroscopic tubes with light introduced through it and bent at an angle so as not to be in the line of vision. With this tube and light, the distal end can be withdrawn further from the object under observation; thus giving a view of a larger area. Here I will say that in the case reported the urine passed by the urethra within seventy-two hours, the catheter was withdrawn and the wound soon closed. It may be asked, of what practical importance will this operation be? If we wish to do the best prostatic surgery, we *must* know the intravesical conditions. Routine operations will not do, and only after a careful study can the surgeon select the operation for each particular case. Occasionally we meet cases in which it is impossible to introduce a cystoscope, stone searcher, or other diagnostic instrument. I believe that in these cases, it is better to attempt to cystoscope the bladder by the method outlined than to choose an operation regardless of intravesical conditions. For instance, if by this method we discover encysted stone, or stone in the postprostatic culdesac, we would hardly select the Bottini operation, although other conditions were favorable for it. So much for its use in prostatic disease. If upon examination by the ordinary cystoscope I should find small polypi, I should attempt their removal through the suprapubic tube, feeling confident that it could be successfully done, and that the patient would be well much sooner than if cystotomy were performed. Since performing the operation reported here, I find that Fenwick has suggested the use of a trocar-pointed cystoscope to find if there be a stone in the postprostatic pouch, whether he has carried the plan into execution I am unable to say. This case, with observations, is offered as a preliminary report of work being done, and with the hope that some genius may give us an instrument with a wider range of usefulness than the one here proposed.

The Etiological Conditions of Acute Rheumatism.—Kr. Thue does not believe that rheumatism is due to pyogenous bacteria, nor to the diplostreptococcus described by Leyden, Wassermann and Meyer. He holds that acute rheumatism is an infectious disease sui generis, the infecting agent of which has not as yet been discovered. Many cases of pseudo-rheumatism of pyæmic basis may greatly resemble rheumatism, but special characteristics, especially in connection with the temperature, will be found by careful investigation. Moreover, acute rheumatism may be complicated by a secondary pyæmic infection. He reports in this connection the case of a young man who was recovering from a typical attack of acute articular rheumatism, when streptococcal angina appeared, with infection of the organism. Streptococci were found in the blood a day or two after the appearance of the angina. The disease, accompanied by irregular fever, lasted for about a month, but complete recovery followed.—*Norsk Magazin for Lægevidenskaben.*

ASEPSIS IN DENTAL SURGERY.

By WILLIAM J. LEDERER, D.D.S.,
NEW YORK.

The writer was prompted to publish this paper through a remark passed by a noted New York surgeon, who, at a discussion of the various causes of osteomyelitis, said, "There is no dentist in New York who operates aseptically." This is, indeed, a rather broad statement to make, and, if true, would cast an ugly slur on the whole dental profession, for every dental chair would be a spreader of disease and a menace to public health. To enlighten the doctor and those who believe what he said, I will state, in short, how asepsis is obtained and maintained in dental practice; and, after reading the account or seeing the actual operation in a dental office, I do not think the speaker would then feel justified in repeating his remark.

As far as the cleansing of the hands is concerned, first. hot water and green soap are used with a brush, the nails carefully cleaned, and then hands rinsed. After that, carbolic soap is employed, and then the hands are rinsed in a cold bichloride of mercury solution. If a patient turns up who is suspected to be a "specific," I make it a practice to use finger cots, which are sterilized by boiling before and after using. This treatment of the hands is about the same as practised by the hospital surgeon, and so there cannot be any complaint as to lack of asepsis.

Now, as far as the sterilization of instruments is concerned, the method employed is as follows: Forceps and all larger instruments are sterilized by boiling in a solution of formaldehyde (¼ to ½ per cent.), before and after use. Hypodermic needles, nerve broaches, and engine drills are passed through alcohol and burned off; then, before being introduced, are dipped into carbolic acid, full strength. For syphilitics a separate set of instruments is employed. So much for the care of the hands and instruments. The technique of aseptic dental operations is as follows: To illustrate it in as few words as possible, and still do justice to the subject, I will quote four cases occurring daily in dental practice and the method of treatment:

1. *A Case of Extraction.*—The patient is requested to rinse mouth with a solution of chlorinated soda; then the tooth is examined by means of a mirror and probe. The mirror is taken from a solution of formaldehyde, 2 per cent., wherein it is always kept, except when in use, as the heat of the sterilizer would destroy it. The forceps has been placed in the sterilizer, and the temperature raised to the boiling point. After the attachment and direction of the roots have been ascertained, as nearly as possible, the tooth is extracted, and the patient is given distilled water with which to rinse the mouth. Forceps and probe are returned to the sterilizer, and the mirror to the formaldehyde solution. If the hemorrhage is of the ordinary type, it subsides soon, and the alveolus is flushed out with formaldehyde solution, and then packed with sterilized cotton, dipped into a carbolic-acid preparation, and the patient is instructed not to remove the same till retiring, as the plug will keep out foreign matter, such as particles of food, etc. The patient is instructed to return the next day, and the alveolus is again washed out, and the patient dismissed.

2. *Caries of a Tooth Which Is to Be Filled.*—First, the carious cavity is wiped out with a pledget of cotton, dipped into a carbolic-acid preparation, then the débris and broken-down dentine are removed by excavators, which have been burned off in alcohol flame, and the cavity is packed with cotton dipped in oil of eucalyptus. Then the cavity is shaped with engine burrs (sterilized), the soft dentine is removed, and the filling material is introduced. Special care is taken to keep the cavity free from saliva either by the application of a sheet of rubber (rubberdam) over the tooth, or the stopping up of Stenson's, Wharton's and Rivini's ducts by the placing of sterilized cotton over them. Then the filling material is introduced. If the nerve is exposed, the same is covered with cement, which is admixed with aristol, and this is mixed with phosphoric acid, and a little eucalyptol. (This is my method; there are many others.) After this mixture hardens, the filling is introduced.

3. *A Case of Pyorrhœa Alveolaris.*—The patient is requested to rinse the mouth with a solution of chlorinated soda or permanganate of potassium. The teeth and roots are carefully scaled with sterilized instruments, and the alveoli are washed out with some antiseptic solution, as the case may require, then packed with cotton dipped in medicaments, according to the indications of the case. In these cases special care as to aseptic proceedings is looked out for, and I have formed a habit of keeping, for the reception of cotton soiled with pus and broken-down tissue, a special vessel, which is always flushed with a bichloride solution.

4. *A Case of Alveolar Abscess.*—The case indicates immediate opening of the abscess. The patient is requested to rinse the mouth with formaldehyde solution. Then the area where the abscess points is wiped off with alcohol, and then full strength of carbolic acid is applied on cotton. Incision is then made with a sterilized bistouri, the pus is evacuated and the cavity washed out. If there is no marked pericementitis, the tooth is opened, the dead pulp removed, and the abscess cavity flushed through the pulp chamber, to obtain thorough drainage. If this is the case, I usually inject carbolic acid, full strength, and, after that, loosely pack the opening in the tooth, so as to allow the escape of gases. The patient is given some antiseptic wash, and dismissed for the day.

These are the ordinary, every-day proceedings of the dental surgeon, and I leave it to the medical profession at large whether these are septic or aseptic operations. I trust that the doctor whose remark brought forth this short paper, and also the readers of these lines, will now see that dentistry, as practised by legitimate practitioners, is not quackery, plied as a trade, by ignorant, unscrupulous individuals, but a specialty of medicine the same as ophthalmology or otology, or any other branch of the science of healing.

823 Park Avenue.

The Toxic Effect of Alcohol on the Ganglion Cells of the Retina.—Harry Friedenwald reports his experiments on the rabbit with pure and commercial methyl alcohol, absolute ethyl alcohol, and essence of Jamaica ginger, made of 95 per cent. ethyl alcohol. The experiments extended over a period of almost four months. There was a high degree of cirrhosis of the liver found in the rabbit fed with absolute ethyl alcohol. The animals were all in apparently good health when killed. The effects of all four substances were alike. The retinal ganglion cells showed marked degeneration and the inner and outer nuclear layers were less affected. It was evident that methyl and ethyl alcohol act similarly on the retina in chronic poisoning, and that the degenerative changes resulting from chronic alcohol poisoning are like those found by Holden and Birch Hirschfeld in acute methyl alcohol poisoning. These are the first experiments in which ethyl alcohol has been used, as well as the first in which degenerative changes have been demonstrated in chronic alcohol poisoning.—*Bulletin of The Johns Hopkins Hospital.*

THE INDICATIONS CALLING FOR OPERATIVE INTERFERENCE IN "GALLSTONES."

By CARL W. [illegible], M.D.

[illegible]

[illegible]

The "bile plant" consists of the liver, gall-bladder, and ducts. The gall-bladder and its system of ducts are lined with mucous membrane continuous with that forming the inner coating of the duodenum, and therefore susceptible to catarrhal and bacterial invasion. Catarrhal and bacterial invasion invariably precedes the formation of gallstones—an important fact, as with this knowledge we may be quite certain that a large proportion of pain experienced in chronic catarrhal gastro-enteritis is due to involvement of the gall-bladder, accompanied by the passage through the ducts of clotted mucous, [illegible] plugs, and possibly, biliary sand. The presence of pathological mucous in the gall-bladder, together with exfoliated epithelia, bacteria, and the [illegible] per cent. cholesterine proportion of the bile itself, affords the nucleus for stones.

In some unknown way, probably chemical, these non-epithelial [illegible] attract to themselves biliary salts, thus growing by accretion, and found to consist of cholesterine, pigment, bacteria and inorganic salts of iron, potash and soda.

Gallstones present many interesting variations; thus in shape and size, from sand to cracked corn, beechnut or nutmeg, in consistency from gelatine to flint, in color from pale yellow to chocolate. It is not, however, to the etiology of this affection that I desire to draw attention, but to the indications for operative interference.

I may be pardoned, I trust, if I digress to state my position regarding the treatment of gallstones (other than surgical) having for its object a radical cure. In my judgment the present-day medical treatment of gallstones is absolutely not curative, but merely palliative in its effects. I do not believe in the theory of the disintegration of gallstones within the gall-bladder or ducts by medicinal agents. Furthermore, I do not believe that any experiment to determine the curative effects of medicinal treatment can be successfully conducted, since such experiment would be surrounded with so much uncertainty that the scientific mind would reject its conclusions—should they be favorable—as altogether unworthy of credence.

The only authentic instance of the disintegration of a gallstone, that I know of, is reported by Dr. J. W. Kime in the *International Journal of Surgery* for October, 1901, where, in a case of impacted choledochus stone, occurring in Dr. Kime's practice, Murphy of Chicago was called and performed cholecystotomy, suturing the cut edges of the gall-bladder and parietal incisions together, thereby establishing free drainage, and trusting to nature to effect the expulsion of the stone by mechanical retrogression, as so frequently happens upon the resultant subsidence of inflammation of the involved ducts, when for sufficient reasons it is deemed inadvisable to subject the patient to the more serious choledochotomy.

The external wound was kept open for eleven months, the stone, however, retaining its position. Choledochotomy becoming necessary, the stone was found to be softened and disintegrated throughout most of its external layers, to the consistency of putty. Murphy thinks this due to contact with atmospheric air during the period of cystic drainage. The inference to be drawn from this is plain.

To resume, the indications calling for operative interference in gallstones are arbitrarily two, i.e., the *elective* and *imperative*. The elective indication is the mere fact of the presence of foreign substances, i.e., mucous plugs, [illegible] bodies, biliary sand, gravel, or stones. The imperative indication is the advent of complications.

The "elective" indication.—The presence of gallstones, in any except the nebulous period of their formation in the gall-bladder, I believe to be always an indication for radical removal, all other things being equal. Such operation is just as safe in uncomplicated cases as interval operations in chronic catarrhal appendicitis.

In view of this, corroborative symptoms of faceted or non-faceted gallstones are, to me, an indication for the elective operation, in which the patient is advised of the prognosis, both as regards the effect of the condition upon the general health and the complications liable to supervene, after which the patient must decide either to take the risk of palliative treatment and procrastination, or elect the radical procedure. We shall not have done our whole duty to our patient until we have done this.

The corroborative symptoms of gallstones are, briefly, the discovery of faceted or non-faceted calculi in stools, after varying recurrence of colic pains in the right hypochondriac and subscapular regions. The stools may be gray in spots or sections. Jaundice may be present in varying degree, and evanescent. Severe spasms due to tentative efforts on the part of the gall-bladder to expel stones, is also an indication of their presence, even though no evidence be present in the stools. Precedent gastro-intestinal catarrh strongly indicates their presence when combined with the above-mentioned symptoms. Spasms due to the passage of mucous plugs or bodies also calls for section, since the best possible treatment for catarrhal cholecystitis, the mother of gallstones, is cholecystotomy, with external drainage. Tenderness upon pressure is not common in uncomplicated cases, but soreness and lameness usually follow these attacks, and remain for a greater or less period.

The imperative indication.—Sooner or later the gall-bladder takes on acute inflammatory conditions from bacterial infection constituting the degrees and forms of cholecystitis, infective, ulcerative, suppurative, gangreneous, as a result of the precedent and ever-present catarrhal condition, the presence of calculi, and lesions and obstructions caused by the latter in their efforts to effect a passage outward. The indications in all these conditions is immediate section and drainage, particularly if there is a distended gall-bladder, threatening rupture, with all that this implies. The symptoms are pain and tenderness in right hypochondriac region, elevated temperature, rigors, jaundice, fulness, and perception of a globular body, by palpation, in the gall-bladder region, and rigidity of the overlying abdominal muscles. An acute attack of biliary calculi, with severe colic, is not an imperative indication to operate unless all the foregoing symptoms accompany. Impaction of a stone, however, in any part of the cystic or common duct, causing rise of temperature, and chills, with varying degrees of jaundice and distention of gall-bladder, is an "imperative" indication to operate to avoid further serious complications, such as rupture, peritoneal infection, hemorrhage, exhaustion, shock, etc.

Report of four cases showing peculiarities.—CASE I.—Mrs. F.; aged forty-five years. Diagnosis, diffuse pelvic abscess; evacuation of half-pint of stinking pus by posterior colpotomy; gauze drain renewed daily; much improved by end of week. When admitted, slightly jaundiced; eight days from admittance severe attack of biliary colic, rapidly jaundiced, urine like concentrated bile, common duct obstruction; patient not in condition to undergo section, on account of septic condition; coma and death in eighteen hours; efforts at elimination, including intravenous saline infusion, utterly futile; death due to extra strain upon already overloaded kidneys in eliminating septic bile; no albuminuria or casts to indicate nephritis.

Case II.—Miss F.; Diagnosis, chronic catarrhal gastroenteritis; has frequent severe colic pains in epigastrium, and passes numerous steatomatous beechnut shaped plugs or bodies in stools, together with large quantities of glairy mucus; has iliocolic tenderness, distended abdomen from flatulent dyspepsia and constipation; no jaundice nor signs of obstruction; gastrointestinal condition treated for six months, with marked improvement; gall-bladder symptoms continue, and are rather more severe; this is a case for "elective" cholecystotomy and drainage, the best possible treatment of gall-bladder catarrh. Operation refused.

Case III.—Mrs. T.; history of gallstones; symptoms of calculus impacted in common duct, jaundice; colicky pains very severe; rigid abdominal muscles over hepatic area; elevated temperature, rapid failing pulse, rigors, gall-bladder tensely distended, presenting to the right of and on a level with the umbilicus; abdomen quite tympanitic, operation "imperatively" indicated, was rapidly performed, disclosing partially gangrenous gall-bladder walls, which, rupturing under the great tension, gave vent to a large quantity of muco-purulent bile fluid. Alongside of the gall-bladder, in the left hepatic lobe, was a large abscess, filled with thick, creamy pus. A large stone was felt impacted in the common duct; no calculi present in the gall-bladder. The duct-stone was allowed to remain and "work out" later, because of the generally unfavorable condition for immediate removal. Drainage was instituted and the stone was delivered in about five weeks, the gall-bladder entirely sloughed away, and fistula closed. Made good recovery and is well after four years. Weight of stone, 47 grains.

Case IV.—Mrs. W.; slight jaundice, fever, chills; pain constant in epigastric region; distension of gall-bladder forming distinct tumor; muscular rigidity over tumor; stools quite natural in color. Diagnosis of gallstone impacted in cystic duct, operation being "imperatively" indicated, section was done, and gall-bladder found to be filled with a pale yellowish, serous fluid, and containing, besides, three calculi, two of large size, faceted, and one, small, brown, and beechnut-shaped. One of the large stones was snugly fixed in the mouth of the cystic duct, like a cork in the neck of a bottle, while the second opposed its faceted surface to that of the lower. The three stones weighed 137 grains. Recovery was prompt and fistula closed in three weeks.

23½ Merchants' Row

Perforation of the Intestines by Ascarides.—Sante Solieri reports the case of a man suffering from collapse and such alarming symptoms, that laparotomy was performed. The peritoneal cavity was filled with pus, fæces, and ascarides. The intestines were distended, reddish brown in color, filled with fecal matter, and deprived of all peristaltic movements; in one of the loops of the small intestine a round perforation was found, which gave issue to fæces and ascarides. The patient died nine hours after operation, and at autopsy the intestines were found to be filled with fecal masses and ascarides, the latter, doubtless, having caused the perforation.—*La Riforma Medica.*

DEATH FOLLOWING AN ENEMA*

By THOMAS HAYES CURTIN, M.D.,
CORONER'S PHYSICIAN, BOROUGH OF THE BRONX,
NEW YORK.

I desire to report a case in which death was produced in a most unusual manner, and the clinical history of which will emphasize strongly two points: (1) The dangers of enemas as used by inexperienced nurses and by the laity; (2) The proneness of the medical profession to account for most abdominal disturbances by looking to the much-abused appendix.

C. D., aged thirty-two years, married, carpenter, no family history obtainable, habits good, four years ago had an attack of pain and tenderness in abdomen, vomiting, etc., for which he was treated for appendicitis and recovered. He has suffered for years with chronic constipation, for which he had to resort to purgatives and enemas. On the evening of February 3, 1902, he was hale and hearty; he partook rather liberally of clams during the evening, and returned home about 10 p.m. He suffered from a little griping pain in the abdomen, and as he was constipated, proceeded to take an enema as was his usual custom and in the following manner: to a long piece of hose he attached a hard rubber nozzle about six inches in length; to the faucet of the bath tub, sat himself in the tub, and inserted the tip into the rectum. I was unable to get any information regarding the result of this enema. About 12 o'clock, midnight, his abdominal pains increased, and he was vomiting. This continued until 7 a.m., when he was seen by his family physician. He found the abdomen distended more prominent on right side, general abdominal tenderness, more tenderness on right side, especially over McBurney's point. Temperature, 103° F.; pulse very rapid and weak. He gave him a soap enema with fair result. At 10 a.m. he saw him again, in consultation; found him in same condition but weaker. Temperature dropped to 102° F. Both physicians agreed on a diagnosis of rupture of an abcess from appendicitis, and advised his removal to hospital for immediate operation. On his arrival there, at noon, the hospital surgeon found him with high temperature, rapid, weak and thready pulse; abdomen distended; general abdominal tenderness, especially over site of the appendix; rigidity of right rectus muscle. Here a diagnosis of acute fulminating appendicitis was made, but no operation was performed, as the patient's general condition would not warrant it.

The patient continued to grow worse and died at 9 p.m., about twenty-four hours after he gave himself the enema.

Autopsy.—Performed fourteen hours after death; body well nourished; rigor mortis relaxing; marked signs of beginning decomposition; case evidently septic; abdomen moderately distended; abdominal incision made. On opening the peritoneal cavity, a large amount of clear fluid gushed out; entire abdominal cavity filled with this clear fluid; intestines covered with fibrin and agglutinated together; all the signs of a beginning septic condition; peritonitis was present; stomach empty; small and large intestines carefully gone over; ileum joins cæcum three inches above normal situation in lumbar region; appendix about four and a half inches long, running upward behind the peritoneum; no evidence of present or former inflammation; the caliber of the sigmoid and rectum was unusually small; both empty; found an old ulcer situated posteriorly at lower end of sigmoid near beginning of portion which was perforated, and the edges of which were [illegible] of any [illegible] tissue.

---

*Report of case, read before N. Y. Celtic Medical Society, February 27, 1902.

The conclusion drawn from the autopsy was that he had either punctured the old sinus with the end of the bulb of the enema tube or that the force of the stream was sufficient in itself to rupture the wall of the gut at the site of the old ulcer. The fluid evidently entered the general abdominal cavity, setting up septic peritonitis causing death.

BILE BURNS IN ANÆSTHESIA

By HERBERT [illegible], M.D.

NEW YORK

[illegible] OF THE NEW YORK ACADEMY OF MEDICINE

Burns of the face sometimes follow upon the administration of an anæsthetic, and upon these occasions it is the custom of the operator to blame the administrator for faulty technique in allowing drippings of the anæsthetizing agent to occur.

Both chloroform and ether will burn the skin of the ordinary subject if poured continually over a part in concentration, but bile altered in its passage through the stomach during the progress of an anæsthesia is capable of producing a similar action.

Bile as formed is alkaline in reaction, and when, either from relaxation or a wave of reverse peristalsis, it gains entrance to the stomach, though that organ be at rest and therefore covered with mucus and alkaline, the mere presence is sufficient to cause an outpouring of gastric juice. Hydrochloric acid in the juice at once decomposes the taurocholate and glycocholate of sodium, salts of the bile, setting free their acids with a resultant fluid vomit easily capable of burning.

Since the profession has been educated during the past few years to know when an anæsthesia is being conducted with the greatest safety to the patient as well as to securing despatch for the operator, it has become the exception to see the violent struggles heretofore the rule, when, instead of the patient taking the anæsthetic, the anæsthetic took the patient, with an ever-present danger to life which, under present-day methods, all must concede is almost wholly removed. At such times it was not infrequent for quantities of the anæsthetizing fluid to be spilled over the patient's face, with danger to his eyes or skin-surface. While this source of possible burning is now happily done away with, it is customary to grease the front of the face with vaseline. The statement that this procedure is not an adequate safeguard from bile and stomach contents vomit will be accepted when the principle of emulsifying oil, which bile has, is recalled.

The case which I saw and which has led me to the conclusion that the irritating qualities of bile are sufficient to cause a burn of the skin, occurred in a lady of fair complexion and fine skin texture, who had been taken with an attack of acute gastritis. After vomiting a quantity of food particles she threw off several ounces of a light yellow and very acrid smelling, watery fluid; within the course of six hours afterward blebs were raised where this fluid had spattered over her bared shoulder and arm, giving the appearance of a scald.

The writer has recollection of two cases of burns occurring after ether had been employed as an anæsthetic in which the administrator claimed to have taken the precaution of applying vaseline to his patients' faces and to have spilled none of the anæsthetic during use. The burns were small in both cases, being about the size of a ten-cent piece, extending outward from the mouth and on the cheek, but healing was slow. In both cases there had been vomiting of a strongly acid, [illegible] fluid.

To prevent any ill effects arising from contact of vomited fluids over the skin of a patient under an anæsthetic, it is simply necessary for the anæsthetist to have ready at hand a towel saturated with a weak soda solution, with which to wipe the patient's face or other exposed parts after the onset of vomiting. It is certain that observers, having their attention drawn to this matter, will be enabled to explain the presence of excoriations and blisterings of their patients after anæsthesia in which vomiting has occurred, and which is otherwise unexplainable to those who study a careful technique in the administration of anæsthetics, and having observed the fact will be enabled to prevent future complaints of this sort.

A CASE OF RESPIRATORY TINNITUS

By PHILIP D. KERRISON, M.D.

NEW YORK

[illegible] UNIVERSITY AND BELLEVUE [illegible], ATTENDING [illegible] UNIVERSITY AND BELLEVUE [illegible]

The following case of tinnitus is perhaps of sufficiently unusual a character to justify a brief account of its development, treatment, and final subsidence.

On the 18th of June last, S. D., a man aged forty-six years, an inmate of the Home for Incurables, appeared at the aural department of the University-Bellevue College dispensary, complaining of tinnitus. The disease for which he had been admitted to the Home had not been positively diagnosed. In the history, kindly supplied by Dr. J. C. Jones, the physician in charge, the following symptoms were recorded: Previous to admittance the patient had suffered with severe headaches, shooting pains in the legs, and great loss of strength. On admission there was partial retention of urine, catheterization night and morning being necessary. Patient complained of a sensation of numbness and cold in the left side of face. Pupils uneven, the left being smaller than the right. Both pupils reacted rather slowly both to accommodation and light. Patella reflex absent on left side, very slight on right. Patient walked firmly and without difficulty, and stood steadily with eyes closed. No symptoms of ataxia. The symptoms, on the whole, had improved during his sojourn at the hospital.

At the dispensary the patient gave the following aural history: He had never suffered from aural disease, either during childhood or later in life, never a pain; never a discharge from either ear. His hearing he considered perfect, except that it was somewhat interfered with by subjective noises.

In April last, and constantly since, he had experienced loud and distressing noises in the left ear. These noises he described as low blowing sounds, like a very low whistle. When asked if the noises were continuous, he said "no, that they came and went as he breathed." When told to fill his lungs and hold his breath, he said that the noises ceased. When asked to breathe rapidly, he said that noises recurred with proportionate rapidity. The patient said that the noise was experienced both with inspiration and expiration. With the noise he described a sensation as if he were breathing through the ear. "When I breathe in, it feels as if it were coming in, and when I breathe out, as if it were going out of the ear." Evidently, then, the noises were synchronous with the respiratory movements of the chest, and were caused by air passing either into the tympanum, or over the pharyngeal orifice of an abnormally open tube. During the examination it was noticed that the patient repeatedly closed the mouth and nostrils and, by attempting to inflate the lungs, drew in the air from the ears. Reversed Valsalva). In explanation of this, he said that by this means he was able to stop the noises, but that they always returned as soon as he swallowed. He denied experiencing any unusual sound or quality in his own voice, so that autophony—which is so often present where the entrance of air into the tympanum is rendered abnormally easy—does not seem to have been among his symptoms.

Physical examination of the ear, nose and pharynx revealed the following conditions:

Left ear (in which the noises were heard).—Drum membrane perfectly healthy in appearance, the position, color, light reflex being absolutely normal.

Right ear.—Normal except for a slight congestion along the handle of the malleus.

Nose.—Ecchondroses from both sides of the cartilaginous septum; slight congestion of the nasal mucosa. (The patient, however, states that he has never experienced any discomfort or difficulty in nasal respiration.)

Pharynx.—Uvula abnormally long, deflected to the left, and lying in contact with the base of the tongue for about one-third of an inch. The pharyngeal walls showed no evidences of acute inflammation.

On inflating the ears by catheter, both Eustachian tubes were found to be patent, the left seeming to be abnormally wide and open.

Functional Examination.—The reactions to functional tests were the same in both ears. Acumeter and whisper heard with ease twenty feet, the limit of the examining room. Lower tone limit, 26 D.V., upper tone limit 1.4—Galton. Weber's test lateralized to the left. Bone conduction, fork 256 D.V., normal in right ear; very slightly increased (?) in left. Upon the above history—mainly upon the apparently unusual caliber of the left tube—a tentative diagnosis of beginning sclerosis in the left tube was made.

Treatment.—With the object of stimulating the mucous membrane of the Eustachian tube, the left tympanum was gently inflated per catheter, a stimulating vapor (containing iodine, menthol and camphor) being introduced. This, it was hoped, would produce increased vascularity, and, perhaps, cause absorption of any newly-formed connective tissue in the tube.

During the following month the patient came once or twice each week to the dispensary, and during this period the treatment above mentioned was continued without affording any relief. During all this time he claimed that he was constantly distressed with the noises already described, his only relief being that temporarily obtained by performing a reversed Valsalva.

On July 29 a bougie was prepared of No. 5 piano wire; the end, wound with cotton, was dipped in an alcoholic solution of bichloride, 1 in 4,000, and this was introduced through the catheter into the Eustachian tube, and carried as far as the isthmus. After a few moments the bougie was withdrawn. A cotton applicator was then bent so as to describe a curve similar to, but rather greater than that of, the Eustachian catheter, and the end, having been wound with a pledget of cotton and dipped in the alcoholic bichloride solution, it was introduced catheter-fashion into the pharyngeal orifice of the tube, and pushed as far into the tube as it could be made to go. This was kept in place half a minute or more. On its withdrawal, the patient expressed complete relief from the subjective noises.

On August 3 the patient returned to the dispensary, stating that the relief afforded by the last treatment had lasted about two hours, when the noises had returned and persisted as before. The treatment as above described was again instituted, with the result that the noises were again relieved. A week later, August 10, the patient returned stating that the relief following the last treatment had lasted nearly two days before the noises returned. On this occasion he received about the same treatment as on the two preceding visits, but for some reason—possibly because the hour happened to be late and the time at our disposal limited—he failed to experience the same relief as before. He left promising to return within a week.

From this time, August 10, the patient did not return to the dispensary until October 1, when he came in response to a note from the writer. In explanation of his failure to return for treatment he stated that shortly after leaving the dispensary the noises had ceased; that since then they had returned only at long intervals, and then had lasted but a few moments, so that the noises no longer annoyed him and he considered himself practically cured.

Objectively his present condition differs but little from that observed on the day of his first visit to the dispensary. The left drum-membrane still presents a normal appearance, and the right still shows congestion along the hammer handle. The uvula no longer rests upon the base of the tongue, the redundant portion having been excised. The pharyngeal roof and naso-pharynx show nothing more marked than a certain degree of chronic congestion. Upon catheter inflation, however, the auscultatory signs are slightly modified on the left side, where the tube seems narrower than when he first came under observation, so that I can no longer detect any difference in the caliber of the two tubes. Both tubes are patent, of rather large caliber, but apparently healthy.

In reviewing this history the chief point of interest, and that which is still unsettled in the mind of the writer, is the determination of the original condition upon which the symptoms depended. Two theories present themselves:

1. That already suggested, of a beginning sclerotic process, originating in the Eustachian tube, and which later would have invaded the tympanum and made itself known there by impairment of function.

2. That, as the result of a mild congestive, or inflammatory process, affecting first the naso-pharynx and later the cartilaginous portion of the Eustachian tube, the walls of the latter were left rigid, and prevented from assuming their normal apposition.

The writer is inclined to regard the latter condition as having been the original cause of the patient's symptoms; and assuming the correctness of this view, it is probable that the symptoms would have disappeared in time without treatment.

Perhaps future attacks may occur to throw further light on this patient's trouble. In the meantime, though kept under occasional observation, he is practically without symptoms referable to the ear.

810 PARK AVENUE.

Syphilis and Marriage.—W. A. Hardaway says that his own rule of conduct has been to refuse professional consent to the marriage of a syphilitic for four full years from the date of infection, this period being occupied with assiduous specific and hygienic treatment; and further, that there should have been at least two years of complete immunity from specific manifestations. But even then he does not think that a medical man is in a position to give absolute and exact guarantees to the patient.—*St. Louis Courier of Medicine.*

How Shall We Treat Sepsis Following Labor and Abortion? B. O. [illegible] gives the following rules: (1) Remove gently with the finger, sharp curette and tenaculum all débris, decidua, blood clots and lingering tissue which may be infected from the uterus and from all raw surfaces of cervix, vagina and vulva. (2) Dry all these raw surfaces and freely apply to them 95 per cent. carbolic acid, washing away the excess by a douche of sterile water. (3) Unless hemorrhage requires, leave no tubes or packing of any kind in either vagina or uterus. (4) Have simple continuous [illegible] vaginal douche used twice a day thereafter. (5) Open the bowels freely with calomel, ⅛ gr. every hour for four hours, then follow with Rochelle salts until sufficient action has occurred. (6) Give 3 gr. sulphate of quinine every four hours followed by 15 drops tincture of chloride of iron in water. (7) Give good nourishment with milk, eggs and stimulants every four hours. (8) Let this be the routine; any treatment and more radical measures will rarely be indicated. (9) Fixation of uterus with infiltration in Douglas' cul-de-sac or ligaments, or pus in tubes or ovaries must be treated by opening and draining through vagina. (10) Multiple abscesses in uterine walls, or infection of walls or pelvic cavity call for removal of uterus and all else necessary by the vaginal route. The abdominal route is in all acute cases dangerous and seldom, if ever, justifiable.—*Annals of Gynecology and Pediatry*, February, 1902.

The Operative Treatment of Chronic Bright's Disease. A. Pousson reports the case of a child of ten years suffering from nephritis with general anasarca and ascites. Paracentesis abdominis had been performed seven times. The author cut down on the right kidney in the loin and found it much enlarged. He made an incision two inches long through the capsule and drained the wound for two weeks; the amount of urine secreted increased from 14 oz. in twenty-four hours to 40 oz. on the seventh day after operation, while the percentage amount of albumin diminished from 1.6 per cent. to 0.8 per cent. The child's condition did not continue to improve and therefore the capsule of the left kidney was removed in its entirety. The child was critically ill for some days subsequently, and unfortunately contracted pneumonia, but he gradually recovered and the renal symptoms underwent a remarkable amelioration, so that while the amount secreted in twenty-four hours ran to 44 ozs., the amount of albumen diminished to 0.04 per cent., the casts were largely diminished in number, the general œdema vanished and the ascitic fluid disappeared. Sixty-two days after the last operation the patient continues to improve. The anæmia has largely disappeared and the albumin is a mere trace. Very few casts are found; no return of œdema or ascites.—*The Canadian Journal of Medicine and Surgery*, March, 1902.

Opium in the Treatment of Some Cases of Intestinal Obstruction.—B. T. Moore relates the history of a woman of seventy-five years with irreducible hernia femoral of the left side. Not being able to have a passage of the bowels, and having other symptoms of strangulation, she took a cathartic and used some taxis with the result of aggravating the symptoms of strangulation. There was a swelling in the groin of the size and shape of a cucumber, six inches long, of an angry red color, and very sensitive to the touch. The woman had vomited repeatedly. After moderate taxis without any result she was directed to take half a grain of opium every six hours, or oftener if necessary to control the pain and to anoint the tumor and adjacent parts with belladonna ointment, and to apply flaxseed poultices over the tumor and the whole of the abdomen below the navel. This treatment was continued for three days when the poultices were abandoned and the lower part of the abdomen and the tumor were painted with collodion so as to form a thick investment. On the sixth day of the opium treatment she had five spontaneous movements, and on the seventh the swelling was soft, [illegible] and little sensitive to the touch. All the symptoms of strangulation, except confinement of the bowels, passed away after the first few doses of opium.—*Massachusetts Medical Journal.*

Symptoms and Treatment of Coal Gas Asphyxiation.—Carl J. Lund describes the symptoms seen recently in a case as consisting of [illegible]; the action of the heart was depressed, the pulse was quickened [illegible] per minute; there was low blood pressure; the cherry-red color of carbonmonoxyl hæmoglobin; rigidity and early opisthotonos; stertorous respiration; slight convulsions during unconsciousness. Treatment consisted in the [illegible] of [illegible] Sylvester's method of artificial respiration, a hypodermic injection of 2 milligrammes of nitrate of strychnine given at once and followed by another of 1 cubic centimeter of ergotol to tone up the relaxed circulatory system. Inhalation of oxygen should be used when this gas is at hand, and next to that in value is dioxide of hydrogen, U. S. P. strength. This patient being unconscious, the following drugs were mixed and introduced into his stomach by a tube: 1 c.c. of tincture of capsicum, 60 c.c. of dioxide of hydrogen, 60 c.c. of pure water. In less than thirty minutes the patient showed signs of recovery. One hour after the first dose of H_2O_2, a rectal enema was given containing 100 c.c. of hydrogen dioxide with 300 c.c. of pure water. The patient became semi-conscious and could swallow a little, and was then given 2 c.c. of H_2O_2 in a little distilled water every thirty minutes for five hours, then every four hours for forty-eight hours. He made a good recovery.—*Northwestern Lancet.*

On the Propagation of Vaccine from Calf to Calf.—S. Emeno describes his method of preparing vaccine by starting with humanized lymph and propagating it successively from calf to calf. He claims that in this way efficacious and safe vaccine may easily be obtained, that the vaccine can be preserved for a long time without deterioration; kept in stock and prepared in large quantities if a sudden demand arises. The conditions of its successful preparation are, that the original vaccine should be of good quality and free from contamination, that the calf should be a vigorous one from two to three months old, that the area of inoculation be about 2.5 sq. cm. per 1 kgm. of calf. The lymph should be drawn off [illegible] hours after inoculation, ground in a mortar and diluted with three times its quantity of a 60 per cent. solution of glycerin, containing carbolic acid in the proportion of 1 to 1.3 per cent. This mixture should be aspirated into a capillary tube, which is then closed at both ends and kept in an ice box after having been kept in a room temperature not higher than 20°. For immediate use it should be kept in an incubator for a few hours, but for long preservation the quantity of carbolic acid should be reduced. The lymph thus prepared is extremely strong, and should be diluted with glycerin water before inoculating the calf.—*The Sei-I-Kwai Medical Journal.*

Snake Venom in the Treatment of Plague.—Hem Chandra Sen considers the fresh venom obtained from strong, young black cobra (keuta variety) the most powerful stimulant in plague. Fortunately, it is an irritant to the bowels, and a hepatic stimulant, so that most of it is thrown out and the danger of poisoning is thus lessened. The author prefers its administration by the mouth, mixed with bile or arsenic, to giving it hypodermically, as in the latter case it is liable to cause disintegration of the red blood cells, which are already in danger of disintegration from the plague itself. The objection made by some scientific men that snake venom is inert when administered by the mouth is met by the statement that in many men now living who have recovered from plague after the administration of snake-venom pills, the medicine caused a burning sensation in the head, which lasted for some time after recovery.—*Indian Medical Record.*

MEDICAL RECORD:

New York, April 19, 1902.

SUSCEPTIBILITY TO DISEASE.

ONE of the impossibilities of medicine as a so-called exact science is that the patient is not always responsive to morbific influences in accordance with any set rule. Thus the two sides of the equation are never balanced in any given case in exactly the same way. All sorts of controlling influences are at work in modifying the generally accepted conditions of cause and effect. There is no such thing as mathematical conclusion in estimating the chances of a positive prognosis in any given case, or in predicating the special action of any particular class of remedies. While we may be well informed as to the laws of disease, the patient himself is the main factor to be taken into account. In the attempt to form an opinion, we are governed by the study of the sick one's proclivities, and of his various and complex receptivities of morbific influences. It is the proper appreciation of these qualities which constitute the judicious and careful practitioner as compared with the careless and off-hand prescriber.

We cannot go far in this method of reasoning without considering the important rôle played by the inherent vital resistance of individuals, not only as regards susceptibility to contagion or infection, but in reference to an equal combative tendency against complications in any given malady. Not only do certain individuals differ from others in hereditary tendencies and in the complex responsiveness to their varied environments, but the same person shows various degrees of resistance at correspondingly different periods. Thus in early life he has one variety of diseases, and later on others—each in its own time and following certain laws which are now very well understood. It is the stroke of the clock on the mark of the hour. The old-fashioned physician, who was not only acquainted with the general constitution of a family, but also with the physical peculiarities of its individual members, always worked to advantage in foretelling the probable outcome of the sickness in question. The probabilities were always in one direction or the other. From many points of view it is a great pity that this kind of knowledge, upon which a prognosis could be most reasonably based, is fast dying out with the growth of specialism and with the fashionable tendencies of patients to be constantly changing medical advisers.

Some of the most interesting facts bearing on hereditary influences have been gathered by tracing the family diseases through different generations in isolated communities. The life insurance companies study the question also on a correspondingly broader and more comprehensive scale, reducing probabilities to almost mathematical accuracies. Thus the life limit fixes the rate of premium for all ages of persons who are apparently in good health at the time the contract of risk is taken. It is necessary to go still further than this if we expect to apply general principles to special physical types. Nordau goes to extremes in generalizations respecting the signs of degeneration. Still, he started rightly, and the facts he obtained in support of his theory are of value as suggestive of a more reasonable plan of study. We are, at least, convinced as to the relation which true physical degeneracy must bear to disease proclivities.

When we adapt general principles to individual cases we must assume, so far as susceptibility to disease is concerned, that the depression of vital force is the first step to that end. In other words, the system must be prepared for the attack by the lowering of physical tone. Susceptibility in such a sense means temporary weakness. At least this admission appears to explain why, when the various causes of disease are constantly operating, the individual escapes attack until the soil is duly prepared for the seed. We see this fact constantly exemplified in the study of the infectious properties of all the common diseases. Pneumonia, typhoid, and tuberculosis serve as apt illustrations of the point in question. In every case the weaker persons are the ready prey for the lurking and ever-ready bacilli. One surgeon, who is overworked and below par, pricks his finger and the infection rapidly multiplies itself, another one eliminates the poison as readily as a duck sheds rain. If we could more accurately determine these relative conditions, how much disease and consequent death might be prevented? In severe and prolonged operations, for instance, we could estimate the chances for the patient with much greater certainty than at present seems possible. We know well enough that one patient survives where another dies. The same kind of operation saves lives on one hand and kills on the other. The point at issue in this cursory discussion on the general subject of susceptibility is to know which is which. It is not impossible to hope that by a more thorough and careful study of this important question we may at no distant period be able to widen observation in each individual case, either by still newer methods of examining the blood, the urine or other of the secretions, or by the proper interpretations of peculiarities in physical construction, the relative chest capacity, the size and strength of the vital organs, the hirsute development, the skin circulation, the pulse rythm, the conformity of the limbs or the metabolic capacity. The important fact is to be discovered somewhere along these lines, and when once it is made plain, we shall have the question of prognosis in any given instance more definitely settled than is possible at present.

Cholera in the Philippines.—On April 13 it was reported that the number of cases of cholera in the islands up to date was 663, and of deaths, 510; the figures for Manila alone being 245 and 192, respectively. Among those attacked in Manila were four Americans, one of whom died.

CARCINOMA AND ITS ETIOLOGY AS REGARDED BY THE SURGEON AND PATHOLOGIST

In Great Britain recently there occurred one of the most illuminating discussions on cancer which has ever taken place among English-speaking people. The opinions advanced by the eminent men who spoke on the subject were not distinguished by originality but the whole question of cancer, and especially of its etiology, was thoroughly gone over and the common-sense view of the matter was presented in good, plain language.

The particular occasion of this symposium was the reading by Sir William Banks, Surgeon to the Liverpool Infirmary, of a paper describing some of his experience in operating for the disease, and the conclusions which he has drawn as to its cause.

Sir William Banks' address was an animated and reasonable presentation of the subject, and although, naturally, he regarded the matter from the standpoint of the surgeon, yet as an operator of thirty-five years' experience, his deductions cannot but be entitled to consideration. Alluding to the much-vexed point as to whether there was or was not a cancer parasite, the speaker said that he was inclined to think that the parasitic theory had a great deal to be said in its favor. He thought that there was a special body in cancer very easily recognizable when one was able to appreciate it, which, at all events, accompanied cancer.

Mr. Plimmer, whose investigations into the cause of cancer have made his name known throughout the world, is, naturally, the most prominent advocate in Great Britain of the parasitic theory, and Mr. Harold Stiles of Edinburgh, the keenest upholder of the degeneration view of the case.

Mr. Stiles believes that the origin of cancer is due to degeneration of the nuclei of the epithelial cells.

Sir William Banks opposed Mr. Stiles' views on the ground that the growing part of a carcinoma was its circumference, and the center was hard—that is to say, it was the point where fibrous degeneration was going on. In the active part alone the parasites were found, and that seemed to him in opposition to the theory of degeneration. Further, in the staining of these cancer parasites the reagents that affected them did not affect the nuclei of the epithelial cells. In his opinion but one cause stood out prominently among the many that had been suggested, and that was the great increase in the amount of food, and notably of meat, which was now consumed by civilized people. It was not drunkenness, syphilis could not be the cause, because among all the women he had seen with cancer of the breast he could hardly remember one whose character was bad. It could not be bad water, bad housing, or bad sanitation, because all cities were in a better state in these days than ever before. The wretched, half-starved patient was not the most prone to cancer, its most numerous victims were well-nourished persons with plenty of fat, and often with the color of health in their cheeks.

Mr. Marmaduke Shields made a strong plea for a stricter classification of the varieties of carcinoma, on the part of pathologists, and doubted whether the explanation of the origin of a slowly-growing epithelioma upon the face of an old man was the same as that of a quickly-growing glandular cancer in the mamma of a woman. His belief was that the mysteries of tumor growth were bound up in the mysteries of cell proliferation as illustrated in the contact of the sperm cell with the ovarian cell, and whoever solved a problem like that would throw light on many subjects otherwise doomed to perpetual darkness.

Of late there has been a growing conviction that an intimate connection exists between cancer and the conditions of nutrition. Some hold and have supported their assertions with numerous statistics, that the consumption of raw vegetables is a prolific cause of cancer. Dr. Lyon of Buffalo read a paper in the spring of last year in support of the view of direct infection by means of raw vegetables, and so eminent an authority as Behla favors this theory.

Roger Williams, on the contrary, writing in the "Twentieth Century Practice of Medicine," inclines to the opinion that over-consumption of meat is a prominent factor in the causation of carcinoma. From returns collected by the British Medical Association Collective Investigation Committee, it appears that of one hundred and ninety-four cancer patients one hundred and twenty-three had been moderate eaters, fifty-nine small eaters, and twelve large eaters. There was not a single vegetarian among them, and only a few had been great eaters of vegetables. That men are more liable to cancer than women in New Zealand and New South Wales is probably due, as Macdonald believes, to their gluttonous habits in respect to meat eating. Roger Williams holds that probably no single factor is more patent in determining the outbreak of cancer in the predisposed than high feeding. Many indications point to the gluttonous consumption of meat, which is such a characteristic feature of the age, as likely to be specially harmful in this respect.

Statistics show that the consumption of meat has for many years been increasing by leaps. When excessive quantities of such highly stimulating forms of nutriment are ingested by persons whose cellular metabolism is defective, it seems probable that there may thus be in those parts of the body where vital processes are still active such excessive and disorderly cellular proliferation as may eventuate in cancer.

It would, perhaps, appear to an unprejudiced observer that those have the greater weight of evidence behind them who think that excessive meat eating has undoubted influence on the causation of carcinoma. The fact cannot be denied that cancer has increased *pari passu* with an increase in the consumption of flesh; and also that in those countries in which meat is most largely eaten the growth in the number of cancer patients has been most marked.

The United States and Australia, and, in a lesser degree, Great Britain, are conspicuous examples of this coincidence.

At any rate, the question of nutrition as regards its influence on the causation of cancer is worthy of much closer investigation than has at present been made.

Without in any way wishing to depreciate the splendid work which has been done by investigators within recent years in their attemps to elucidate the mysteries of cancer, it would not, perhaps, be amiss it many of them were to take to heart the advice tendered them by Sir William Banks at the close of his address. He spoke as follows: "I sincerely hope that more caution will be observed in the pronouncements that pathologists and others may make in the future than has hitherto. been observed. Quite recently one gentleman has brought forward some views from which the most important results were expected, but the wonderful bodies which he has discovered turned out to be nothing more than cells from the corks of his bottles."

The parastic origin of cancer has not been nearly proved; indeed there is as much to be said for the the belief that the disease is derived from degenerations and dropsical changes in the nuclei, as for the former theory.

Our hope, with regard to clearing up the matter, rests upon the promise that in the near future the cancer problem will be investigated by the foremost scientific men of several countries, untramelled in their efforts by lack of funds—the obstacle which has, up to the present, more or less seriously hindered research work everywhere. In this respect the United States, thanks to the generosity of her rich men, will be able to strive for the goal on an equal, if not on a better, footing than any other country.

RECOMMENDATIONS FOR THE RETIREMENT OF SURGEON-GENERAL STERNBERG WITH THE RANK OF MAJOR-GENERAL.

Surgeon-General George M. Sternberg, U. S. Army, who now has the rank of brigadier-general, has made formal application to be retired with the rank of major-general at his coming retirement for age on June 8, next. Special legislation is required for such action, and the application has been forwarded to Congress with the favorable endorsement of the Secretary of War and Adjutant-General. Under present laws, officers of the Navy who served in both the Civil and Spanish wars are retired with an increased grade, and it is only just that the same consideration should be shown to officers of the Army who have had equally long and distinguished service. Under this law Surgeon-General Van Reypen of the Navy was recently retired with the rank and pay of rear-admiral, corresponding to a major-general; and there is every reason why the same grade should be given to the head of the Medical Department of the Army, whose responsibilities —from the greater size of the latter and the conditions under which it serves—are much heavier, and whose duties are more arduous.

In his application General Sternberg calls attention to the fact that his forty-one years of service include the entire period of the Civil war, the war with Spain, the Philippine Insurrection, the relief expedition to Pekin, two Indian campaigns, and professional service in several epidemics of cholera and yellow fever.

General Sternberg was brevetted a captain and later a major for gallant services during the Civil war, and was subsequently brevetted a lieutenant-colonel for gallant services in 1877 against the Nez Perces Indians under Chief Joseph. As a bacteriologist, sanitarian, scientific investigator and author, his services to humanity and the science of medicine have been twice rewarded with the degree of LL.D.; and he has been made President of the American Medical Association, The American Public Health Association, The Association of Military Surgeons, and a member of many scientific societies. He has repeatedly represented the Medical Department of the Army at national, foreign and international medical congresses.

To ignore his request for the consideration already granted others is to disregard a career which can scarcely be equaled for long and honorable military service, gallantry in battle, self-sacrificing heroism in epidemic disease, valuable work as a scientific investigator, and admirable administration of official duties.

A strong memorial has been presented to Congress by the legislative committee of the American Medical Association, consisting of Dr. H. L. E. Johnson of Washington; Dr. Wm. H. Welch of Johns Hopkins University; and Dr. W. L. Rodman of Philadelphia, urging that proper recognition be given to Surgeon-General Sternberg's services, and that he be placed on the retired list with the increased rank for which he has applied. Certainly no one is more worthy of such consideration than General Sternberg, in the honoring of whom the profession should itself feel honored.

Tuberculin as an Aid to Surgical Diagnosis.

Dr. J. M. Elder, Lecturer on Surgery and Clinical Surgery, McGill University; and Surgeon to the Montreal General Hospital, read a paper before the Montreal Medico-Chirugical Society, October 18, 1901, giving notes which he had gathered in the Montreal General Hospital with regard to the use of tuberculin, as an aid to surgical diagnosis, and the deductions he drew therefrom.

The tuberculin used was supplied by Dr. Trudeau of Saranac, and Dr. Elder regretted that he had not more than one kind of tuberculin, in order to try one where the other failed.

The object in instituting the series of experiments was an effort to answer the following queries: (1) In what class of surgical cases due to tuberculous infection does the use of tuberculin give most aid as a diagnostic agent? (2) Is its use followed by any untoward symptoms, either local or constitutional? (3) How long after its infection should we expect the rise in temperature which shows the typical reaction? (4) Is the reaction constant when tuberculosis is present?

Four cases in which tuberculin was used under the direction of Dr. Elder showed reaction and in three the results were negative. In all cases which were operated on after administering the serum the pathological reports verified the clinical diagnosis, and in all care was taken to give the serum only after the temperature had been observed for several days, in order to exclude, as far as possible, accidental variations after giving the serum. The temperature was taken every two hours, and this, says Dr. Elder, should be kept up for thirty-six hours at least, as the reaction is sometimes delayed.

The observations led to the following answers to the questions which Dr. Elder had set himself:

1. That tuberculin is valuable as a diagnostic

and in suspected lesions of glands, synovial sacs and bones. In tuberculous peritonitis it gave no reaction.

2. Its use was followed by no untoward symptoms either local or constitutional.

3. That the reaction, as shown by rapid increase in temperature, varies in time, appears only in acute cases where lesions are large, and should be looked for even as late as thirty-six hours afterwards.

4. The reaction does not appear constant even when tuberculosis is undoubtedly present, but on the contrary in no case did we get any reaction when tuberculosis, so far as we could determine otherwise, was not present.

The conclusions arrived at by Dr. Elder are in the main similar to those reached by former observers. The tuberculin test is by no means an unfailing one, but in certain forms of tuberculosis is a valuable diagnostic agent, and as its use is—not according to the majority of authorities—followed by harmful results, its merits in deciding whether a tumor is of tuberculous, syphilitic, or neoplastic origin, though not undoubted, are yet considerable in their aids to diagnosis.

The International Sanitary Congress at Havana.

In Public Health Reports, March 21, is a report to the Surgeon-General, United States Marine Hospital Service, by P. A. Surgeon G. M. Guitéras on the above congress.

Dr. Juan Santos-Fernandez of Havana delivered the presidential address. In the course of his remarks he referred to Dr. Finlay as the discoverer of the method of transmission of yellow fever by the mosquito, and, for this and other reasons, he thought that Cuba was entitled to be selected as the gathering point of periodical pan-American sanitary conferences. Continuing he said: "It is consequently a proximate result of this sanitary congress, held today in Havana, to spread, no doubt, in all Latin America the news of the progress realized here in Cuba in the study of yellow fever, the rumors of which were carried away by the members of the third Pan-American Medical Congress who came from these countries—rumors that are now transformed into certain and distinct sounds and unquestionable truths."

The greatest amount of interest was centered in the paper read by Lieut.-Col. Valery Harvard, Surgeon U. S. A., entitled "Recent Advances in the Study of Yellow Fever." It gave a detailed account of the work of the United States army commission, supported the proposition that, so far as known, the Stegomyia fasciata was the only means of transmitting yellow fever, and that, therefore, prophylactic and quarantine measures should, as far as possible, be based upon that fact.

These conclusions did not, by any means, meet with universal approval, and several speakers combated in animated language the now widely accepted theory that the mosquito is alone responsible for the dissemination of yellow fever.

Immediately after the close of the general session, President Santos-Fernandez called a meeting of the official delegates to hear the reports of the committees appointed at the previous meeting, and to discuss the resolutions to be adopted by the Congress. Lieut.-Colonel Harvard was called upon for his report, and presented the following resolutions:

1. That the Stegomyia fasciata is, up to the present time, the only means demonstrated for the transmission of yellow fever.

2. In accordance with the above, prophylaxis should consist in the destruction, as far as possible, of this species of mosquito, and the best means should be adopted to prevent these mosquitoes from gaining access to persons ill of yellow fever.

3. That quarantine measures against yellow fever shall be based thereon.

The first two resolutions gave rise to little adverse criticism, but a stout opposition was offered on the part of many of those present to the adoption of the third.

Dr. Glennan, speaking for the Marine Hospital Service, stated that its representatives could not accept the proposition in its present form, and that it was necessary to bear in mind that in the reformation of quarantine regulations against yellow fever it was necessary to take into consideration the opinion of the health authorities of the Southern United States.

The president and others suggested that the third proposition should be left out, but Colonel Harvard insisted upon its retention.

Upon the matter being put to vote, the third resolution was rejected and the first and second were unanimously accepted.

It has, undoubtedly, been proved definitely that the Stegomyia fasciata is the principal means of transmitting yellow fever. Nevertheless, the demonstration that the aforesaid mosquito is the sole agency whereby the disease is conveyed has not been as yet entirely conclusive. As long as there be any doubt with regard to the point, it would seem reasonable that quarantine measures should be wide enough to cope with all possible modes of spreading infection.

Reports of the United States Army General Hospital, Presidio, Cal., for 1900 and 1901.

These reports have recently been published by Lieut.-Colonel Alfred C. Girard, Deputy-Surgeon-General United States Army, the medical officer in command.

In the report for 1900 an interesting history is given of the establishment of the hospital, together with a detailed description of the buildings. During the fiscal year ending June 30, 1901, the institution was greatly enlarged, among other additions being a power-house and a building to be used as a chapel or library for the hospital.

Unfortunately, however, in the early part of June, 1901, the northeast portion of the hospital was destroyed by fire, necessitating the expenditure of a large sum for reconstruction.

The total number of patients admitted to the hospital during the fiscal year 1901 was 5,587, of whom regulars numbered 2,813; volunteers, 2,278, and discharged soldiers, 496.

The patients have been derived from the following sources: Transports from the Philippine Islands, admissions from the model camp, Presidio, San Francisco, Cal., admissions from civil life in the case of discharged soldiers, and readmissions from various sources.

During the year there have been 182 deaths, divided as follows: Regulars, 74; volunteers, 96; discharged soldiers, 12.

The nosological index of diseases treated in the hospital from July 1, 1899, to June 30, 1901, show that diseases of the digestive system stand first in order of frequency; infectious diseases, second; accidents and injuries, third; diseases of the respiratory organs, fourth; diseases of the nervous system, fifth; diseases of the muscles, bones and joints, sixth; diseases of the genito-urinary system, seventh; diseases of the integument and subcutaneous connective tissue, eighth; diseases of the circulatory system, ninth; diseases of the ear, tenth; diseases of the eye, eleventh; diseases of general nutrition, twelfth; diseases of the nose, thirteenth.

The greatest number of deaths occurred from chronic dysentery, although the mortality rate was low.

The treatment of this disease at the Presidio hospital has varied considerably. In the amœbic cases the treatment, which has proved very successful, has habitually been by quinine injections. In the forms of dysentery other than amœbic the treatment by sulphate of sodium or magnesium sulphate has been used in the more acute cases with much success, and often in the chronic cases the treatment by magnesium sulphate has resulted in many cures. Injections of nitrate of silver have been used rather extensively, and in many instances with good results. One of the greatest objections, however, to this method of treatment, is the intense pain which the injections cause, and which, in some instances, has been so severe as to preclude their use. Bismuth subnitrate and opium have not been used to any extent in the Presidio hospital in the treatment of dysentery.

The report of the bacteriological laboratory of the Presidio hospital, under the charge of Contract Surgeon Charles F. Craig, is of exceptional interest, but, owing to lack of space, it is impossible to more than refer to the investigations here. At another time the matter will be dealt with at length.

One hundred and eighty cases of insanity were received at the hospital during the fiscal year, and with regard to its etiology the report reads as follows: "The etiology of insanity in soldiers returned from the Philippine Islands is a subject which is at once simple and complex. Without doubt a large proportion of the cases which become insane have a hereditary taint which had not been discovered prior to enlistment. This, taken with the long distance from home, the intense heat of the tropical sun, constant harassment by an enemy which it is impossible to see, excessive use of alcoholics, and the depressing influences always present in a tropical climate, will account for the changed mental condition. . . . Almost all of the cases of melancholia will, upon examination, be found to be due to nostalgia, and, as a rule, in these cases the prognosis is very favorable, provided the patient is transferred to the United States. It would be uninteresting and of no value to consider the etiology of the different forms of insanity present in soldiers, for all of them will, upon examination, be found to be due to one or more of the causes mentioned above."

The United States Army Medical Hospital at Presidio has in its short life performed efficiently the services for which it was established.

THE EDUCATION OF THE DEAF-BLIND.

The *Review of Reviews* for April contains an excellent article by Ruth Everett on this subject. The history of the development of the education of these unfortunate members of the human race is given, and it is shown that to France, and particularly to one of her sons, the Abbe de l'Epée, is due the honor of being the pioneer in the systematic education of deaf-mutes; he laid the foundations for the sign language.

Dr. Samuel G. Howe, an American, did the same service for the deaf-blind, and the whole American system of the education of the blind is the outgrowth, declares Miss Everett, of Dr. Howe's individual work and experiments in that field of action.

By his successful education of Laura Bridgman he proved, contrary to the opinion of all the eminent authorities of the day, that it was possible to educate a deaf, dumb, and blind person.

The training of an individual thus afflicted is manifestly attended with countless difficulties, and requires on the part of the instructor the possession of a superabundance of patience, zeal, and tact.

Miss Everett sums up the course of teaching in the following words: "The deaf-blind is taught to associate a point sign with each letter of the manual alphabet, and with his stylus and a slate prepared for the purpose, or a writing machine for point, prick the points on a soft piece of paper that will take and hold them. After the child has learned to read and write, it may be said that, with industry, patience, and perseverance, it is within his power to open many a gate that leads into pleasant places. The deaf-blind study their letters from raised print; to facilitate recitations, a typewriter is generally used. The writer discusses at some length the sign language, the oral system, and the combination of the two, and expresses herself as satisfied that the use of signs and the manual alphabet does not interfere with the knowledge of lip-reading and oralism, and, in support of this view, quotes Mr. Wade, one of the best-known authorities, who gives these reasons for his belief. First, because no pure oralist was ever able to read his lips, while three, using the manual alphabet and signs, did so."

Miss Everett concludes her article by instancing several remarkable examples of the efficacy of the education of the deaf-blind conducted on modern lines.

Health of the City of Manila.—The report of the Board of Health of Manila for the month of January, just received, states that during the month the general health of the city was good, the death rate comparing favorably with that of many cities located in the temperate zone. The Board says, however, that until many radical sanitary defects are removed or remedied, the mortality among the lower classes will remain above the average. The damp and humid habitations of a large proportion of this class, says the report, are a potent cause in elevating the death rate. As a general rule, on account of the humidity, the lower stories of houses in Manila are unfit for sleeping purposes. Before a proper sanitary condition can be reached, the report states that it will become necessary to make a number of permanent improvements which will involve the expenditure of large sums of money. The principal municipal improvements needed are a modern sewerage system, increased water supply with filtration beds, better drainage and suitable parks.

During January the death rate in Manila was 30.33 per thousand. The report calls attention to the fact that out of a population of 300,000 there was not a single death from smallpox, scarlet fever, or diphtheria. No case of plague occurred during the month, though eighteen cases occurred during January, 1900, and four in January, 1901. In 1900 plague was most prevalent in March, while in 1901 the maximum intensity of the disease was reached in May, when 124 cases occurred. The report states that radical measures for stamping out plague are being enforced. These include the cleaning out and disinfection of houses in which cases of plague have occurred, or in which rats affected with the disease have been found; the destruction of rats by traps and poison; the immunization of the lower classes, among whom the disease usually occurs, by means of the Shiga antitoxin; the thorough cleansing and disinfection of all filthy habitations, and the prevention of overcrowding. It is believed by the Board that the enforcement of these measures and the exercise of continued vigilance on the part of the sanitary inspectors will result in the complete elimination of plague from the city of Manila.

News of the Week.

A Triumph for Lunacy Examiners.—Mrs. Julia N. [illegible] of 153 West Thirty-fourth street, New York city, was brought to the Pavilion for Insane, Bellevue Hospital, September 12, 1897. She was found to be insane, and a commitment being made it was presented to Judge George P. Andrews of the Supreme Court, who committed her to the Saint Vincent's Retreat. Her husband then decided that he wished to take her home instead of sending her to the asylum, whereupon he was asked to sign the usual contract used at Bellevue in such cases, showing that it was against the advice of the physicians that she was released, and stating that he was to assume the entire responsibility for the same. It was later shown that he had great trouble with her during the months that followed, and that he was frequently obliged to leave home for weeks at a time to avoid the actual violence to which she subjected him; but notwithstanding this fact it was October 18, 1898, before he made another move in the matter. He then sent two physicians, Drs. Austin Flint and Allen Fitch to examine her, report, and advise with him in regard to the future course to be pursued. They told him she was undoubtedly insane and ought to be sent to some institution for custodial care, as a recovery could not be hoped for; but, before the necessary commitment could be procured, she became so violent that a policeman arrested her in the street and arraigned her in the Fifth District Police Court on a charge of insanity. Magistrate Deuel committed her to the care of the Commissioners of Public Charities to be examined. On the morning that this occurred the husband went to the office of one of the physicians whom he had previously employed to make the examination, whereupon a petition was made, signed, and sworn to by the husband, and a certificate of lunacy was later made out and signed by the physicians. This was presented to Judge William N. Cohen later in the day at the Supreme Court Chambers, who promptly signed the same. Upon this paper being shown to the Superintendent at Bellevue Hospital, where the woman was found about five o'clock of the same day, he discharged her upon Judge Cohen's order, which it contained, to the authority of the Long Island Home at Amityville, N. Y., where she was taken that night. A writ of habeas corpus was immediately applied for by a lawyer that she met in the police court, and Judge Cohen discharged the woman to the custody of this lawyer, making this note upon the papers: That, inasmuch as the physicians who signed the commitment did not inform him that the woman was committed at a police court for examination at Bellevue, and also did not tell him that they had not examined the patient at that hospital, material facts had been concealed from him in making the commitment, consequently, he would discharge her for that reason. An application had been made to the court for a trial of the case before a commission in lunacy and a sheriff jury before she was discharged by Judge Cohen, but the unique position taken by him in the matter constantly crept into the case, and resulted in a disagreement of the jury. The commission, also, were not able to agree, as they voted but two to one for insanity; whereupon a suit for damages was immediately brought against Drs. Austin Flint and Allen Fitch, who signed the certificate of lunacy, and Dr. Orville Jay Wilsey and the Long Island Home corporation for $100,000 each. The case came up for trial on Wednesday and Thursday of last week before Judge David Leventritt and a jury. The Judge, however, without hearing any defense whatever, dismissed the complaint upon its presentation by the plaintiff's attorney, thereby taking it out of the hands of the jury. In making this decision he made a special allowance of $500 to each of the several defendants, besides the costs of the proceedings, which amounts to over $300 more. The physicians are to be congratulated in the matter because they declined to settle the suit when they could have done so for $350, which would have been far cheaper to them, besides, the very considerable amount of trouble involved in fighting the case to an issue. But they now have the benefit of a decision which cannot fail to work good to all who examine and make certificates of lunacy for the commitment of the insane.

A Bill to Create a Commission of Public Health.—Mr. Cockrell (by request) introduced a bill to establish a commission of public health and fix the salaries of the commissioned officers of the Marine-Hospital Service. It provides that the commission of public health, which shall consist of one commissioner of public health, appointed by the President, from senior officers of Marine-Hospital Service, and an advisory board, composed of the Surgeon-General of the Army, the Chief of the Bureau of Medicine and Surgery of the Navy, a representative of the Department of Justice, versed in international law, and the Chief of the Bureau of Animal Industry; and the members of the advisory board to serve without additional compensation or emoluments.

It also provides that the Marine-Hospital Corps shall consist of 108 officers; one commissioner of public health, who shall receive an annual salary of $4,000 and shall supervise the office and discharge all the duties as now performed by the Supervising Surgeon-General of the Marine-Hospital Service; and thirty-five surgeons, who shall receive a salary of $2,500 per annum; and seventy-two passed assistant and assistant surgeons, who shall receive an annual salary of $2,000 and $1,600 for their respective grades. Also, that the commissioner of public health shall promulgate all needful rules and regulations for the guidance and discipline of the officers and employees of the Marine-Hospital Service, and shall, in conference with the advisory board and with the approval of the President, make all needful rules and regulations for their enforcement relating to national sanitation in all its foreign and interstate relations, for the hygienic laboratory, and for the several departments in the enforcement of the provisions of this Act and existing laws.

Further, it shall be the duty of the commissioner of public health to collect and diffuse information upon all matters affecting the public health; to advise the several departments of the Government, the executives of the several States and Territories, and health authorities on all questions of public health, to secure the best sanitary condition of vessels, their cargoes, passengers, and crews, from domestic or foreign ports; to prevent the introduction of contagious and infectious diseases into the United States and their spread from one State or Territory and the District of Columbia; and to cooperate with and aid the State and municipal health authorities in the execution and enforcement of such needful rules and regulations as are deemed necessary to suppress contagious and infectious diseases.

The commissioner of public health is to invite annually the several State and Territorial boards of health to delegate one of their members to meet in Washington for the purpose of conferring on matters pertaining to the public health, and to take such action as will tend to secure the co-operation of State, Territorial, and municipal boards in guarding against contagious and infectious diseases in the United States, and to provide a uniform system of registration of vital statistics, and also, by co-operation with the proper health authorities of foreign governments and municipalities, endeavor to extend to the United States a reliable system of international notification of the existence and progress of cholera, yellow fever, typhus fever, smallpox, bubonic plague, or of other contagious diseases within their respective governments.

The President is authorized, when requested by the commissioner of public health, to detail officers from the several departments of the Government for duty in the hygienic laboratory.

Meeting of the British Association for the Prevention of Consumption.—The third general meeting of the association for the prevention of consumption and other forms of tuberculosis was held during the week ending March 22, under the presidency of the Earl of Derby. The report for the year recorded that King Edward had consented to become patron of the association, and that the Prince of Wales had accepted the position of president. During the year branches were formed in several cities, and the treatment and prevention of consumption, the erection of sanatoria, and similar work, was reported to be making good progress. The report added that in the future, progress should be hoped for more particularly in the following directions: (*a*) The suppression of indiscriminate expectoration as a danger and a nuisance; (*b*) the universal adoption of voluntary notification of phthisis in all towns and districts; (*c*) The general recognition of the fact that foul air is as great a menace to the public health as foul water; (*d*) The establishment of sanatoria, as far as possible, on self-supporting lines for the working classes. Sir William Church, Sir William Broadbent, and others took part in the proceedings.

Female Nurses for Bellevue.—A rumor is current that all the nursing at Bellevue Hospital will, in the near future, be performed by women. At present, men who are trained at the Mills School are employed to nurse patients of their own sex in Bellevue, while women graduates from the Bellevue Training School for nurses have the care of the female patients. It is said that the undergraduate male nurses are considering the advisability of raising the question as to the women violating the intentions of the founder of the school in taking charge of the male wards.

Tuberculosis in Cattle.—A series of experiments, extending over more than a year, has just been completed at the Storrs State Agricultural College, Mansfield, Conn., by Professor H. W. Conn of Wesleyan University, to test the accuracy of the statements made by Professor Koch in regard to the relation of bovine tuberculosis to that of man, and its significance to the dairy herd. Professor Conn says that his experiments show that the danger of the spread of tuberculosis through the milk of diseased animals is not so great as has been commonly supposed, but that, in the earlier stages of the disease, when the udder is not affected, the danger from the use of the milk appears to be limited. He says, however, that it is impossible for a farmer to tell accurately when the udder will become affected with the tuberculous germs, and that the only method for freeing the herds of cows in the country from the greatest danger which menaces them is to segregate every animal upon which the tuberculin reacts.

Dr. W. H. Doty, Health Officer of the Port, has received from the directors of the Pan-American Exposition at Buffalo the award of a gold medal for his exhibit on sanitation. The exhibit consisted of models of boats, quarantine plant, islands, with photographs and other material.

The Late Dr. Ervin Alden Tucker.—*Whereas*, an inscrutable Providence has removed from our fellowship an honored member, Ervin Alden Tucker. A.M., M.D., suddenly, in his prime, with only the first sheaf of life's harvest garnered; and

Whereas, the fellows of the New York Obstetrical Society, from long association, have grown into a knowledge of his rare qualities and exceptional equipment for the high sphere of usefulness he had made for himself in his profession; and

Whereas, as members of his own guild and calling, thereby entering into a juster appraisement of his skill and capacity, the fellows of the New York Obstetrical Society especially esteem their departed brother for his unusually long, painfully laborious and self-contained preparation in the hospital wards; his tireless fidelity as observer and statistician; his methodical evolution of a technique in obstetrics; his soundness and directness as a teacher, carrying his formative influence through medical graduates of the last decade to bedsides far beyond his personal ken; his kindly, active, almost paternal, interest in each individual of the large family of medical men he himself selected from the city hospitals and trained as obstetricians; his cohesive power in holding the hospital alumni in fraternal bond; his quiet self-poised yea and nay, which inspired in patients a merited confidence, marvellously rooted; his clean life; his high conception of the responsibility and dignity of the holy office of ministrant at the threshold of life;

Therefore be it Resolved, that the fellows of the New York Obstetrical Society spread upon their records their pride in the fame of their honored fellow, their appreciation, not only of his individual work, but also of the spiritual power of his completed and crystallized life-lesson, which will ever be a stimulus to younger men in the profession;

Be it further Resolved, that a copy of these resolutions be conveyed to the bereaved family as a token of sympathy, appreciation, and consolation in that our brother, "though dead, yet speaketh."

In witness whereof,

E. C. Savidge, M.D.,
J. C. Edgar, M.D.,
G. L. Brodhead, M.D.

New York Academy of Medicine, Section on Otology, Resolutions on the Death of Edwin M. Pyle, M.D.—*Whereas*, it has pleased the Almighty to suddenly call from us our esteemed and respected colleague, Dr. Edwin M. Pyle, and

Whereas, for several years past he had zealously devoted himself to the special field of otology, distinguishing himself in the hospital by his unselfish industry and superior skill as an operator, and winning in these meetings the esteem and admiration of his colleagues for his sincerity of purpose and genuine devotion to the advancement of this branch of medical science,

Therefore be it Resolved, that while we accept submissively the decree of Divine Providence, the members of this Section,as associates in the field of otology and as co-workers in the New York Eye and Ear Infirmary, to which deceased was attached, desire to record the sense of loss which they have sustained in the sudden taking away of their fellow practitioner, and,

It is further Resolved, that the members of this section extend to the family and friends of the deceased their heartfelt sympathy and sincere condolence in their bereavement, and that these resolutions be spread upon the records and a copy be sent to the family and to the medical journals for publication.

(Signed) James F. McKernon, M.D.
Frank L. Blodgett, M.D.
[illegible] Kendrick, M.D.
Committee on Resolutions.

Government Control of Therapeutic Sera.—Senator Spooner recently introduced a bill into Congress to regulate the sale of vaccines and therapeutic sera in District of Columbia and to regulate the interstate traffic in the same, the intention of which is to place the manufacture and sale of all such agents under the direct control of the National Government as represented by the officers of the Marine Hospital Service. The following is a summary of the bill as published in *The Times*.

It penalizes by fine or imprisonment, or both, in the discretion of the court, the taking from one State to another, or the sale, barter, or exchange of any virus, therapeutic serum, toxin, antitoxin or analogous product for use in the treatment of diseases in human beings, unless the same is produced at an establishment operating under license from the Treasury Department. Every package of such organic perparation which may be legally taken from one State or Territory to another for sale or use shall bear the name, address, and license number of its maker, and the date at which it may be expected to lose its therapeutic value. Establishments working under license from the Treasury Department are to be at all reasonable times open to inspection by its authorized representatives or agents. The action of the Secretary in granting or revoking licenses for the domestic production of such preparations shall be taken on the recommendation of the Supervising Surgeon-General of the Marine Hospital Service, and none of foreign production shall be received into the country unless the foreign producers shall permit the same inspection of their establishments as is provided in the case of licensed manufacturers in this country.

A Pension for the Widow of Dr. C. S. Taft.—A bill recently passed Congress providing a pension for Mrs. Sarah Frances Taft, widow of Dr. Charles Sabin Taft, late Acting Assistant Surgeon United States Army, the first surgeon in attendance upon President Lincoln after his assassination. Dr. Taft was born at Lyons, N. Y., and received his education there and at Carroll College, Wis. At the outbreak of the Civil War he enlisted and was stationed at Washington. At the close of the war he was ordered to Texas, where he remained until about seventeen years ago, when, after resigning, he removed to New York. He lived during the latter part of his life at Mount Vernon, N. Y., where he died December 18, 1900, of a cancerous affection of the throat. As Dr. Taft had been a contract surgeon, his widow, under the law, was not eligible to a pension, and it was only by act of Congress that she could be placed on the roll.

New Pest Hospitals for New York City.—Dr. Lederle, the Commissioner of Health, has asked the Board of Estimate and Apportionment for $1,025,000 with which to provide new hospitals for the treatment of contagious diseases, and to repair the old ones. The contagious disease hospital plant, he says, so far as its permanent characteristics are concerned, is now in a state thoroughly discreditable to the city, though in spite of resultant difficulties, the efficiency of the working staff has not been reduced, 5,638 patients having been cared for in 1901 against 2,748 in 1898, the first year of consolidation. Two buildings for the reception hospital at the foot of East Sixteenth street, one small building at Kingston avenue hospital in Brooklyn, and five small pavilions at North Brother Island cover practically all the additions to the city's contagious disease hospital plant in the last ten years. Bronx, Queens and Richmond boroughs are absolutely without such institutions. In proof of the need the Commissioner said that recently two cases of smallpox were discovered in remote parts of Staten Island and a department diagnostician had to travel forty miles and the department steamboat *Franklin Edson* sixty miles before the patients could be landed at North Brother Island. The Medical Advisory Board urges upon the Board of Estimate the appropriation asked for, and advises that the money, if obtained, be spent as follows: *Borough of Manhattan.*—Two pavilions, administration building, annex to Willard Parker, power house, laundry, crematory, morgue, disinfecting plant, alterations, repairs, fixtures, architects' fees, etc., $600,000. *Borough of The Bronx.*—Administration building, four pavilions, station for disinfection, ambulance service and power plant, with fixtures, architects' fees, etc., $100,000. *Borough of Brooklyn.*—Two pavilions, power house, alterations, repairs, fixtures, architects' fees, etc., $125,000. *Borough of Queens.*—Administration building, four pavilions, station for disinfection, ambulance service, power house, with fixtures, architects' fees, etc., $100,000. *Borough of Richmond.*—Administration building, one pavilion, station for disinfection, ambulanee service, power house, with fixtures, architects' fees, etc., $50,000. *North Brother Island.*—Alterations, repairs and additions to present buildings, with necessary fixtures, architects' fees, etc., $50,000.

The Board of Health of Westfield, N. J.—At a meeting of the newly-organized Board of Health in Westfield, N. J., held last week, Dr. J. B. Harrison was reappointed township physician and president of the board, and J. M. C. Marsh was elected secretary. E. Edgar was reappointed sub-inspector. Three disinfecting machines have been purchased, and the Board is now prepared to cope with any contagious disease.

The San Francisco Board of Health.—The Mayor of San Francisco, recently removed the Board of Health of that city, on the absurd ground that it had incorrectly reported the presence there of bubonic plague, and so had brought injury to the city and State. In place of the deposed members he appointed Drs. A. S. Alder, J. Coplin Stinson, T. A. Rottanzi, and M. E. Van Meter.

Health of Troops in the Philippines.—During the month ending February 15 the percentage of sickness among the troops in the Philippines was 6.39, a slight increase over the rate for the previous month, and due largely to measles introduced from transports carrying recruits. Malarial fevers showed an increase during the month, but this was more than compensated for in the decided falling off of gastric and intestinal diseases from 31.0 to 18.50. Bubonic plague has not as yet appeared among the troops.

The Results of Oil Treatment of Mosquito Pools.—The South Orange, N. J., Village Improvement Association, which initiated a campaign of extermination against mosquitoes last summer, has decided to resume its labors in that direction this year. In a circular just issued the Society draws these conclusions on the results of the work of last season: "An immense improvement was made in localities where it was comparatively easy to get at and place oil upon the stagnant water. No perceptible improvement was noted where there were large pools of water difficult to treat with oil. Tall grass and weeds in low spots add greatly to the difficulties of finding stagnant water and applying the oil. It is unwise to depend upon property owners to attend to the oiling. Wherever complaints arose of mosquitos being numerous a breeding place could be found within a few hundred feet of the locality complained of. Drainage in some localities is absolutely demanded."

The Late Dr. W. W. Johnston.—A public meeting of the Medical Society of the District of Columbia was recently held in Washington in memory of the late Dr. W. W. Johnston, perhaps at the time of his death the most prominent and successful physician in that city. The large hall of the Columbian University, in which the meeting was held, was crowded to the doors. Eulogies were pronounced by Drs. S. S. Adams, A. F. A. King, Henry D. Fry, and Geo. M. Koper, all of Washington, and by Dr. William Osler, of Johns Hopkins University, and Dr. Walter Reed, U. S. Army. Announcement was made that steps had already been taken to endow a hospital in memory of Dr. Johnston. With reference to the charitable work done by Dr. Johnston during his thirty odd years of practice, it was stated that this, computed at the lowest rates of the District Medical Society, would have had a money value of more than one million dollars.

New Treatment for Cataract.—The New York *Herald*, March 30, announces that a Bordeaux oculist, M. Cadel, has taken up, with remarkable success, the treatment of cataract without operations, by the application of baths of salicylate of soda. He has, he declares, arrested the progress of opacity in the crystalline lens for several years in numerous cases, and is sanguine of success if the treatment is begun at an early stage.

Dr. William W. Keene of Philadelphia was elected an honorary member of the German Surgical Association at the recently held thirty-first annual session. He has also been appointed honorary president of the first Egyptian Medical Congress which will be held in Cairo, in December of the present year.

Philadelphia Neurological Society.—At a stated meeting, held March 25, Dr. Max H. Bochroch exhibited "A Case of Adiposis Dolorosa." The patient was a woman with huge masses of fat depending from the upper arms, the buttocks and loins and the thighs, while the forearms and hands, the legs and feet, and the face preserved their normal proportions. The fatty deposit was the seat both of spontaneous pain and of tenderness. Dr. F. Savary Pearce exhibited "A Case of Adiposis" in a colored woman, in whom, however, the element of pain was wanting. In other respects the clinical picture was much like that presented by the case first exhibited. Dr. Wm. G. Spiller read a report of "Two Cases of Involuntary Muscular Contractions of the Face," the one being an example of spasmodic tic, in which great relief was conferred by applications of electricity. The other occurred in a patient with paralysis agitans without tremor, and the movement was thought to be of associated character. Dr. Spiller reported also "A Case of Primary Degeneration of the Pyramidal Tracts without Muscular Atrophy." Dr. A. A. Eshner read for Dr. S. Weir Mitchell a paper entitled "The Muscular Factors Concerned in Ankle-clonus." It was shown that when ankle-clonus is excited, with the leg placed in the situation most favorable for inducing this reflex movement, namely in that of slight flexion, the soleus alone is the responsible factor, the gastrocnemius being relaxed by reason of its attachment to the femur. Dr. Chas. K. Mills presented "A New Scheme of the Zones and Centers of the Human Cerebrum." Dr. John K. Mitchell described "An Unusual Form of Foot-clonus" occurring in a woman with lateral clonus of the foot, and clonus of the great toe in addition to other phenomena of exaggerated reflex activity, lateral nystagmus and scanning speech. Drs. Chas. K. Mills and J. W. McConnell described "A Group of Brachial and Pectoral Reflexes" in a man presenting symptoms suggestive of meningo-myelitis. When the outer extremity of the clavicle was struck with a percussion-hammer, the forearm was slightly flexed on the arm, and when the upper portion of the sternal attachment of the pectoral muscles was struck, some of the fingers were extended.

Philadelphia County Medical Society.—At a stated meeting held April 9, Dr. W. S. Wadsworth exhibited a heart displaying a gunshot wound near the apex, with secondary gangrene of the wall of the ventricle, and hemopericardium, and hemothorax from injury of an intercostal artery. Dr. David L. Edsall read a paper entitled "The Diagnosis of Chronic Diabetes Mellitus, and the Urinary Findings in this Disease." He pointed out the distinction between mere glycosuria of alimentary origin or transitory occurrence and true diabetes with the symptoms of profound metabolic derangement. The discrimination from dextrose of other substances in the urine simulating it can be made, in addition to the reduction of copper and of bismuth, by means of fermentation with yeast, and especially the use of the polariscope. Dr. J. P. Crozer Griffith read a paper entitled "Diabetes in Children," in which he referred to the rarity of the disease in early life and the gravity of the prognosis at this time. There appears to be an inverse relation between age and the severity of the disease. Dr. Walter L. Pyle read a paper entitled "Ocular Affections Associated with Glycosuria, with Especial Reference to Central Amblyopia." Dr. H. M. Christian read a paper entitled "The Clinical Significance of Various Forms of Hematuria."

Obituary Notes.—Dr. W. D. MIDDLETON, chief surgeon for the Chicago, Rock Island and Pacific Railway system, and dean of the medical department of the State University of Iowa, died on April 5, at Davenport, Ia., of blood poisoning, following a wound received in an operation performed for gangrenous appendicitis. Dr. Middleton was a graduate of the Bellevue Hospital Medical College in 1868. He was professor of surgery in the Iowa State University, and surgeon to the Mercy Hospital, Davenport.

Dr. JOSEPH H. GALLAGHER died at his home in Brooklyn on April 9, of pneumonia, at the age of twenty-six years. He was born in Brooklyn and was graduated from the Long Island Hospital Medical College in 1898, subsequently serving as surgical interne at St. Catharine's Hospital.

Dr. JOHN L. EDDY died suddenly of appolexy at his home in Olean, N. Y., on April 6. He was born in Rutland, Vt., in 1829, and was graduated from the Castleton, Vt., Medical College in 1854. He served as a surgeon during the Civil War and for many years he was surgeon for the Western New York and Pennsylvania Railroad. He was President of the New York Society of Railroad Surgeons and a member of the National Association.

Correspondence.

OUR LONDON LETTER.

(From our Own Correspondent.)

[illegible]

London, [illegible]

The new Royal Warrant for the Army Medical Service [illegible] welcomed with mixed feelings. [illegible] War Minister [illegible] War Office [illegible] in anything that will [illegible] by the [illegible].

There has not been time at [illegible] for full criticism, but a hasty comparison of the warrant with the report of the committee which preceded it shows that some of the most [illegible] points have been changed, i.e. the number of examinations for promotion proposed by the committee have been reduced, but there are still sufficient to disgust the really well-informed officer. He is to enter the service by competitive examination—if the War Office can attract competitors—but a further examination must be passed before he is made a captain, and yet another before he obtains his majority. If he passes the last with distinction it will accelerate his promotion to the next rank by a few months, but before he attains it, yet another examination stares him in the face. The officials profess to desire to attract the very best candidates to the service, but they seem rather blind to think that the pick of the schools are enamoured of the [illegible] examination craze. The most desirable candidates have as a rule already had enough of grinding for examination and are intent on real practical work.

The warrant gives no indication of an increase in the strength of the Royal Army Medical Corps, nor of the burning question of Indian pay—two really vital points [illegible] study leave. If the medical service of the army is to continue to be undermanned, and the Indian grievance unredressed, the new warrant will be as worthless as its predecessors in attracting the pick of the schools. These young men have heard of the breaches of faith which have been perpetrated by the War Office and have no confidence in vague official promises. They ask for definite pledges—they would do well to demand guarantees against the dodges by which their predecessors have been oppressed and robbed.

Some of the points of the warrant are more satisfactory. The Director-General is to have increased rank, the officers are promised an increase of pay, and special pay and charge pay are authorized. Officers of the Royal Army Medical Corps are to be eligible for brevet rank—a reward for special service hitherto denied them. Distinguished service, whether in the field or otherwise, is also to receive recognition.

The success or failure of the warrant will depend on the sincerity with which it is administered. To attain initial success the War Minister should pledge himself not to suffer the permanent officials to tamper with it.

The Lettsomian lectures this year were delivered by Mr Pearce Gould. The Medical Society was fortunate in its selection of a lecturer. The course is intended to be practical, and Mr Gould took for one of his subjects "Varicose Veins," on which he discoursed with great clearness, the outcome of careful observation and considerable experience. The common view that the condition is due almost if not entirely, to obstruction to the return of the venous blood through pressure above was repudiated by the lecturer. He accepted the view that varicose veins are rather to be regarded as venous overgrowths, a superabundant development of venous tissue—in a word, venous angioma. In support of this he pointed out that in the great majority of cases varicose veins make their appearance before growth is completed—this he had found to be the case in at least 80 per cent. of his patients. It is quite a common observation that patients, when varix appears, are otherwise in excellent health and their tissues generally sound. Nor do we commonly see any signs of obstruction. Œdema, lividity, etc., are conspicuous by their absence, and yet, in other cases, when venous obstruction is the undoubted cause how serious are these symptoms. An ill-applied bandage, slightly impeding the venous return, will very quickly give rise to congestion and œdema below. In graver cases of valvular cardiac disease, or the growth of tumors, or plugging of a main vein where the obstruction is gradual but persistent we are [illegible] the [illegible] is greatly [illegible].

Nor then can we accept enlargement of superficial veins as evidence of obstruction in the deep channels into which they open. Further the [illegible] of [illegible] and [illegible] before the [illegible] theory. Pregnancy has often been held to [illegible] evidence in support of the obstruction theory, but Mr Gould [illegible] this argument. He showed that [illegible] after [illegible] the baby. Large numbers of uterine tumors are attended with varicose less often than pregnancy [illegible] to be restored [illegible]. Of 323 cases treated by Mr Gould 213 were men and [illegible] two women, although in his hospital he had more female than male beds. Mr Pearce Gould formulated his view that varicose veins are [illegible] overgrowths, in support of which he instanced their irregular distribution, their relation to trauma, their hereditary character, and their frequent persistence through many years without injury to the function and structure of the parts from which they receive their blood. A varicose vein contains an increase of tissue. This is often said to be fibrous, but Mr Gould has found it quite as much muscular and endothelial hypertrophy. Associated with the overgrowth there is usually a failure of the valve apparatus permitting regurgitation from the main deep vein into the superficial veins. This Mr Gould has found to be almost constant.

Trendelenburg, in 1891, believing that insufficiency of the valve at the opening of the internal saphena had a great part in causing varix below, proposed to divide the upper end of this vein between two ligatures, and the operation has been freely practised.

Mr Gould published in 1899 the results of fifty cases. At this lecture he presented a table of fifty more cases. This only includes those whose present condition could be given. He has operated on twenty others from whom he has not received a report to date. He concludes that Trendelenburg's operation is simple, safe, and applicable to nearly all cases, that it relieves pain, stops further development of varices and often leads to shrinking or even disappearance of the varices, also exerts a strong influence in preventing thrombosis. Its good effects are most marked when regurgitation into the superficial veins is [illegible]. Its superiority to excision is greatest in cases of widely-distributed and [illegible] varices, as it exerts its influence on all veins which empty into the saphena trunk. It is, therefore, useful in these widely distributed, even general varices of the lower limb, in which excision is inapplicable. To ensure success the obliteration of the vein or veins must be effected quite at their junction with the deep vein.

The way in which medical officers in the service are omitted from court functions is one of the reasons that the King's Commission is not popular. As an illustration, the Surgeon-General of the District—who is the next officer in seniority to the General commanding—was not invited to the official dinner at the King's recent visit to Devonport. Of course the King knows nothing of these slights on his medical officers by the court clerks who make out the lists. They will continue and the service will not gain the popularity it needs until His Majesty is made aware of these slights notwithstanding promises (too often broken) of war ministers and warrants.

There have been some rather unusual law cases. A nurse sued Dr Law for damages for treating her by hypodermic injections of morphia through which she alleged she lost her health, etc. She seems to have become an habitual morphia taker. Many such persons blame the doctor for first giving them the drug just as drunkards declare they began under medical advice. However, it is an extraordinary thing for a nurse, who had been treated gratuitously, to sue for £5 000 as compensation. The judge expressed a strong opinion that an action ought not to have been brought. The jury stopped the case when Dr Law had given his evidence, saying they did not want to hear more. But, though the doctor thus triumphs with the sympathy of court and jury, he is necessarily at considerable loss, for the nurse, of course, has no money with which to pay the costs. What a pity Dr Law did not belong to one of the defence societies?

A grateful patient, a wealthy lady, presented Dr Price, who had attended her for ten or eleven years, with checks amounting to £800 during 1899 and 1900. One was a Xmas present for £100. The largest sum (£300) was partly in recognition of his work as trustee of an institution founded by the patient, who died in 1900

Her executors applied to the courts to have these moneys returned, on the ground that the lady did not ask independent advice as to giving them. Yet these executors did not dare to charge the doctor with using undue influence, and their counsel made quite a point that no imputation on the doctor's honor or kindness to deceased was intended. Moreover, the sum was but a moderate one compared with deceased's estate, which amounted to £90,000. Nevertheless the court ordered the doctor to return the money and pay the costs of the action, on the ground that the relation of patient and physician is a confidential one, and where that exists the donor must have had competent, independent advice before a gift can be supported. There is no exception to this rule of law. It is unfortunate for Dr. Price that he does not seem to have known this, or he might easily have asked his patient to consult her solicitor and let him remit through her banker; or, perhaps, these very executors might have been consulted, and thus prevented from grasping at the small percentage of the estate.

The Midwives' Bill is postponed until June, and preparations are being made for opposing it by various amendments.

Smallpox continues its variations. Yesterday there were fifty-four new cases, on Monday seventy-two, and on the intermediate days forty-one and forty-two. The opposition of the antivacs continues to give rise to ludicrous incidents in and out of Parliament, where most absurd questions are put with the object of discrediting the preventive.

Sir William S. Church was almost unanimously re-elected president of the Royal College of Physicians. The King has permitted his name to remain as an Honorary Fellow of this college as well as of the College of Surgeons.

Preparations for the annual meeting of the British Medical Association at Manchester are in a forward state. There are to be seventeen sections. At the meeting at Manchester, twenty-five years ago, there were only six.

Book Reviews.

OUTLINES OF ANATOMY. A guide to the Methodical Study of the Human Body in the Dissecting Room. By EDMUND W. HOLMES, M.D., Demonstrator of Anatomy, University of Pennsylvania (1892-1901), etc. Second Edition. Lancaster, Pa.: New Era Printing Co., 1902.

THERE are few changes from the first edition of this little dissecting room guide, as it appears in its present form. A schedule of dissection for twenty-eight days is arranged, and if the student follows this he will have dissected the whole body pretty thoroughly. The book is not a quiz compend, and pretends to no such use. It is of convenient size for the pocket.

A RETROSPECT OF SURGERY DURING THE PAST CENTURY. The Hunterian Oration of the Hunterian Society, 1901. By JOHN POLAND, F.R.C.S., Surgeon to the City Orthopædic Hospital, etc. London: Smith, Elder & Co., 1901.

To give a retrospect of the progress and achievements of surgery during the nineteenth century, is to call attention to all that is most important in this branch of science. The lecturer in this instance need hardly have done more than give a list of the more important discoveries and advances in order to impress us with the advantages which a patient has now over one fifty or sixty years ago. The discoveries of anæsthesia and of antisepsis naturally stand out preeminently in a lecture of this kind, but considerable space is devoted to the subject of x-rays, to which the author accords a high degree of importance. The lecture in its present form makes a very readable discourse.

MANUAL OF PHYSICAL DIAGNOSIS for the use of Students and Physicians. By JAMES TYSON, M.D., Professor of Medicine, University of Pennsylvania, etc. Fourth edition. Philadelphia: P. Blakiston's Son & Co., 1901. 12mo; 298 pages.

PROFESSOR TYSON'S diagnosis has been for so many years a standard work that the usual attempts in improving successive editions have been virtually unnecessary. The present edition has been revised and some new matter added, but, altogether, the work is not changed in any essential particular.

HANDBUCH DER PHYSIKALISCHEN THERAPIE. Herausgegeben von Dr. A. GOLDSCHEIDER und Dr. PAUL JACOB. Teil II. Band I. Leipzig: Georg Thieme. 1902.

THIS work on physical treatment, previous numbers of which have been reviewed, continues to present the various subjects in a most scientific and careful style. There are fifty-five illustrations in this volume. The first chapter is on skin therapy, by Dr. C. Kopp of Munich, covered in forty-three pages. The next on muscular affections, the next on joints and gout; then follow infectious diseases, metabolism, and diseases of the respiratory tract, to which Friedrich, Gutzmann, Fraenkel, Egger, and Renvers have contributed.

Readers of German will find here all that pertains to baths, gymnastics, massage, electricity, non-cutting operations, such as intubation and aspiration, and other physical methods, well described.

VENEREAL DISEASES.—A Manual for Students and Practitioners. By JAMES R. HAYDEN, M.D., Chief of Clinic, and Instructor in Venereal and Genito-Urinary Diseases, College of Physicians and Surgeons. Third and Revised edition. Philadelphia and New York: Lea Brothers & Co. 12mo., 292 pages.

THE third edition of this little volume contains new sections on vegetations and herpes progenitalis, and also many new illustrations. As a whole, it is an excellent and concise book for the student.

XAVIER BICHAT. Anatomie Générale appliquée à la Physiologie et à la Médecine. Steinheil, Paris, 1901. 2 vols, octavo, 1,100 pages.

XAVIER BICHAT, one of the great geniuses of medicine, born in 1771, lived, thought, achieved an immortal name, and died in 1802 at thirty-one years of age. His father was a physician. After obtaining his academical degree he began the study of medicine at Lyons, but was soon attracted to Paris by the wide fame of Desault, a surgeon and one of the foremost minds of the day. Shortly after his arrival in Paris he attracted the attention of Desault, who took him into his house, and it was under the guidance of this great man that Bichat continued his studies.

Possessed of an indefatigable activity, of a brain capable of grouping facts and details, and seeking for these facts from the laboratory, the hospital and the post-mortem table, and not from the inaccurate and misleading books of his day, he went farther and faster in a few years than most men do in a whole lifetime. The experiments that he made are remarkable both for their number and originality.

In consequence, Bichat stood at the beginning, and as a founder, of a new era in medicine, for he classified the many isolated items of knowledge and turned empirical, chaotic groping into logical, methodical research. Thus he founded Histology, the science of tissues; General Anatomy, Pathological Anatomy, rational therapeutics, and left such a mark on physiology that for long decades physiologists were wont to entitle essays "Progress of Physiology since the days of Bichat." The object of the Anatomie Générale is:

"To study with precision the properties of living bodies, to show that every physiological phenomenon is finally due to these properties, that every pathological phenomenon is due to their increase, dimunition or alteration, and that every therapeutic phenomenon has for prime object their return to the normal condition; to state the cases in which each is called into play; to distinguish in physiology and in medicine that which comes from the one from that which comes from the others; consequently to determine in a rigorous manner which of the normal and pathological phenomena obey physiological and which physical laws; that is the general doctrine of this work."

"The relation of law and phenomenon as cause and effect is a well-known axiom in physics, chemistry, astronomy, etc. If this work establishes an analogous axiom in the physiological sciences, it shall have fulfilled its purpose."

And that is what he does in this work. It is anatomical physiology more than anatomy. He shows the various systems not merely as anatomical specimens, but alive, in action.

After a consideration, along the broadest lines imaginable, of the tisues in general, he takes up each of the great systems separately, osseous, vascular, nervous, etc. Each is systematically treated as to its general anatomical and histological features; its physical, then physiological properties; its development.

While this is not a work on pathological anatomy, the subjects are enriched by the vast knowledge which he acquired at the post-mortem table, for he gave a tremendous and lasting impulse to this study. In his time, some one here and there did make post-mortem examinations, but never systematically. In the space of a few months, Bichat opened some six hundred bodies and demonstrated the immense advantage that might be derived from their study.

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 10, 1902.

Myokymia.—G. L. Walton reports the case of a man who has had persistent muscular quivering for the past [illegible]. The calf muscles are most affected, but the tendency to quivering [illegible] the body are subject to the quivering, which is [illegible] that of progressive muscular atrophy. There is no [illegible]. This condition has been [illegible] for twenty years, and then [illegible] gradually. It is not to be confounded with paramyoclonus multiplex, and has nothing in common with the electric chorea of Dubini or with the [illegible] chorea of Morvan. [illegible] it is not [illegible].

The School in Its Effect upon the Health of Girls.—L. G. Brackett, [illegible] the importance [illegible] of the school [illegible]. The school is responsible for many of the conditions found among our women in so far as its demands interfere with the usual and necessary amount of sleep and out-of-door play, in so far as by a competitive or ranking system it [illegible] during the periods of accelerated growth [illegible] demands on the mental powers, and in so far as it trains the mind at the expense of the body. It is responsible in so far as the system fails to recognize individual variations in the child and especially between the boy and girl, and thus fails to adapt the training to the individual need, for the method is not only not adapted to girls as individuals but not even to girls as a whole. At the developmental stage statistics show that there is a large number of girls who are distinctly below par, who show evidences of distinct neuroses and who are working dangerously near or beyond their fatigue limit. Of the children who enter the hospitals in consequence of physical developmental defects, hardly more than 5 per cent. are boys.

The Effect of Public School Education upon the Health of the College Girl.—Jane Kelly Sabine says that the type of the American student is better now than it was ten years ago because of the influence of gymnastics and athletics in the lower schools. Bicycling, golf, and increased interest in all out-of-door sports have also done much to raise the standard. Nevertheless the faults of the American type would still be marked, namely, flat chest, hollow back and prominent abdomen. Observation of 2,000 students in finishing schools showed defects in eyesight and hearing and especially marked menstrual difficulties, 75 per cent. being found with irregularities dating from puberty, 60 per cent. had to give up from one-half to two days, and 90 per cent. had leucorrhœa. Since these defects date from the time when menstruation first takes place, when habit neuroses are most easily formed, when morbid sensitiveness keeps the girl at work in school, the reconstruction in her education must be made in the preparatory schools. For whatever position in life she is to occupy she needs good, sound health. Education at the expense of health is worthless. A sound mind in a sound body is a priceless possession; the college girl should represent that type.

Journal of the American Medical Association, April 12, 1902.

The Bacillus Coli Communis in Human Infections.—A. J. Lartigau presents the following conclusions: (1) The B. coli communis is widely distributed in the normal body and in nature. (2) It may, under what seem normal conditions, be carried during life from the intestine to healthy [illegible]. (3) Agonal and post-mortem invasion of the tissues is common, occurring with great frequency under the most diverse circumstances with or without apparent lesion of the mucous membrane of the intestine. (4) The virulence of the bacillus coli communis is influenced by at least two factors: (1) changes in the physiologic activities of the intestine; (2) growth in new host environments. (5) The rôle of this organism as a primary exciting factor in infection is infrequent. It is as a secondary invader of tissue previously damaged by other organisms, or of tissue already injured from other causes, that it claims our chief attention. (6) The bacillus may induce inflammatory lesions mainly in [illegible] of the body [illegible], [illegible] infection may originate in the intestine. (7) Its rôle in acute inflammatory lesions of the intestine, more particularly of the appendix, peritoneum, and urinary passages, has been generally overestimated. Where it may be the primary inciting factor, other organisms usually take this part, the bacillus coli communis [illegible] acting as an accessory factor. (8) It is a factor of importance in the [illegible] of [illegible].

Report of Cases Treated with Rontgen Rays.—W. A. Pusey reports cases of tuberculosis of the skin, epithelioma, [illegible] of the breast, sarcoma, [illegible] of the [illegible] and at the [illegible], [illegible], keloid, and [illegible]. The paper is well illustrated, and the author's conclusions seem to show that the rays cause a degeneration of [illegible] of [illegible] tissue, and [illegible] of the same. He believes that a [illegible] to the rays in the [illegible] diseases above mentioned. The indications for the method are as follows: (1) In all cases of malignant disease which have [illegible] as [illegible] to [illegible] as a prophylactic measure. (2) In all [illegible] cases of malignant disease [illegible]. (3) In all cases [illegible] a possibility of relieving pain and a possibility of [illegible] the progress of the disease. The advantages of [illegible]: (1) It is painless. (2) It destroys diseased tissue, but leaves the healthy tissue in its place. (3) It leaves small scars. (4) It can be used in cases where the surrounding healthy tissue cannot be sacrificed. (5) Hence it is available for cases in which ordinary methods involve deforming operations and serious permanent disfigurement, as, for example, about the eye and nose. (6) It is available in cases in which ordinary methods are impossible because of the amount of destruction of tissue which complete removal would require. In other words, it is applicable to many inoperable cases. (7) It often relieves pain.

New York Medical Journal, April 12, 1902.

A Phenomenon Observed on the Tongue in Acute Malarial Infection.—Lucien Lofton calls attention to the fact that in acute malarial infection the tongue exhibits one or two (generally two) dark lines, running from the base of the organ to the apex, and usually separated by a clearly-defined tract of clean mucous membrane about one-sixteenth to one-eighth of an inch wide. These lines are pyramidal in appearance, and begin among the large papillæ at the base of the tongue. They vary in width and may be from one-eighth to one-quarter of an inch wide, gradually coming to a point in the middle of the tongue. In color they resemble the stain of a 10 per cent. solution of potassium permanganate that has been exposed to the air for some time. They are quite different from the discoloration seen in users of tobacco and snuff, and, when once carefully noted, are thereafter easily recognized. This condition will most likely be found from one day to two weeks after exposure or inoculation. It remains in some individuals longer than in others, notably in the negro. It is more beautifully defined from six to twelve hours after the initial sporulation, and remains until the system is thoroughly cinchonized.

Surgical Shock from a Clinical Standpoint.—Eugene Boise takes exception to the prevailing view that shock is due to a paresis of the circulation, especially of the heart and arteries, and believes it to be due to a profound disturbance of the entire vasomotor and sympathetic systems. This disturbing influence may reach the vasomotor center through various channels, as, for instance, by direct irritation of the sympathetic nerves in abdominal operations, by crushing injury to the skeletal nerves as in railroad injuries, and through the medium of the brain, as in sudden fright. Or two or more of these factors may unite as a causative influence, as in railroad injury, where the influence of sudden and great fright is added to the crushing of the large nerve trunks. The condition induced is essentially an excessive vasoconstriction. As measures of relief Boise advocates the use of nitrite of amyl, strychnine (which, in very large doses, paralyzes the vasomotor centers and so induces vasorelaxation), and saline solution thrown into the veins. The latter should be given at a temperature of 115° or 118° F. Thus administered the heat of the solution is brought directly to the irritated ganglia, and vascular spasm is relieved.

American Medicine, April 12, 1902.

A Case of Parotitis Iodica.—Enrico Castelli reports the case. The patient was a man of forty-seven years. The writer, after diagnosing arteriosclerosis, prescribed potassium iodide. In ten days the patient was in bed, the eyes were watery, and the eyelids œdematous, and he was also suffering from coryza and from ptyalism. There was a swelling in the region of both parotids. Pressure on the parotid, opening of the mouth, swallowing, and mastication were very painful. The iodide was stopped, and in nine days the swelling and all the other symptoms disappeared. Some days later the treatment was resumed and the symptoms returned. The treatment was stopped and again the symptoms ceased. The evidence of parotitis iodica seems undeniable in this case.

Rheumatic Appendicitis.—William A. Edwards gives the following résumé of his paper: (1) The present state of our knowledge does not warrant the use of the term rheumatic appendicitis; (2) There seems to be but two conditions in which rheumatism can at all be considered in etiological relation with appendicitis, and these are when a rheumatic endarteritis of the single appendicular artery exists and when the blood supply is greatly diminished thereby. It seems to be pretty well conceded that the entrance of fecal matter of itself does not necessarily give rise to appendicitis, but it is probable that the inflammation may have its origin in the microorganisms conveyed to the interior of the organ by the fecal matter. Even if rheumatism is an infectious disease, and the infection is due to staphylococci whose seat is in the gastro-intestinal tract, it is not improbable that the fæces in these cases are usually toxic; but this, again, is far from proved, so that when considering a so-called rheumatic appendicitis we must resort to the old Scotch verdict "not proven."

Spontaneous Rupture of the Heart.—Don D. Grout gives notes on three cases of this kind, which he has observed. It is interesting to note the similarity of age, size, and location of the ruptures, and weight and condition of the hearts and arteries, in these cases. All three patients were men, and the ages were respectively sixty-five, sixty-eight, and sixty-nine years. Autopsy in the first case, five hours after death, showed the pericardium filled with partially coagulated blood; the weight of the heart was fifteen ounces, it was evidently fatty, and the coronary arteries were atheromatous. A complete rupture, nearly an inch in length, was observed in the lower anterior portion of the left ventricle. In the second case, autopsy was performed thirty-six hours after death. The pericardium contained about 1½ pints of partly coagulated blood. The heart weighed 15½ ounces. A rupture one inch in length was found in the anterior wall of the left ventricle near the apex. The condition of the heart and coronary arteries was practically the same as in the first case. Examination of the third case revealed practically the same condition of heart muscle and coronary arteries as was found in the first two cases. The rupture, also, was about the same as to size and location. Disease of the coronary arteries is probably the most important factor in bringing about the pathological condition necessary to produce rupture of the heart. An interesting point in the second case reported in this article is the evidence of the length of time that intervened between the inception and culmination of the rupture, which was probably about seventeen days. It is positive, at any rate, that it was fully seven days.

Medical News, April 12, 1902.

The Etiological Classification of Varicose Veins of the Legs.—William S. Terriberry first makes a broad distinction between those cases which occur with predisposing cause, and those in which there is no acquired or congenital defect in the vascular apparatus. Further, with or without predisposing cause, all cases of varicose veins may be placed in three groups: (1) The cases due to regurgitation following stenosis above the saphenous valves; (2) The cases due to regurgitation with stenosis inferior to the saphenous valves; (3) The cases due to stenosis without regurgitation.

Spa Treatment of Gout.—Charles C. Ransom, after discussing various theories concerning the cause of gout, states that at present we must be content to accept the fact that we are dealing with faulty metabolism, the cause of which we can only surmise, and base our treatment upon general principles of hygiene. For this reason, the spa treatment seems to be the proper method of procedure. He first describes the bath, which is given in three stages. The preparatory stage is that in which the body surface is put into a receptive condition by means of exercise, or warming the skin with hot blankets, the hot-air bath, or the douche bath. The treatment stage consists in the application of the thermal stimuli in such order and intensity as to produce precise results, as regards heat production and abstraction and the avoidance of injurious reaction. The correct method will depend upon the condition of the patient. In the reaction stage the object is to retain or intensify the results of the bath. After the bath the patient should be covered with warm sheets and be rubbed dry. The internal use of water is always of great value to the gouty. As to diet, the writer believes that, in spite of the many diverse theories, a mixed general diet which contains a fair proportion of vegetable food, will, on the whole, be found most rational and satisfactory. Exercise is also of great value. As to climate, a dry, inland region of moderate altitude will generally be found the best. Sudden changes in temperature are harmful. Exposure must be guarded against. A pleasant environment is very beneficial. In spa treatment the patient is under much better control than at home. For treatment of joints there are various measures that may be employed locally. One of the most important of these is the local douche. Massage of the joint is also used, as well as the hot-air treatment. Lately, static electricity has been used with excellent results.

The Philadelphia Medical Journal, April 12, 1902.

Rubella and the "Fourth Disease."—J. P. Crozer Griffith declares that, as far as his own experience goes, he can see no possible reason for, and every reason against, the assumption of the existence of a "fourth disease." He believes that every infectious disease is liable to variation in its type, both in the individual and in the epidemic, and that aberrant cases and forms, and even aberrant epidemics arise. A new name cannot be given to each of these. The history of rubella shows that it is peculiarly liable to vary. There is still entirely lacking the most important evidence of all that any "fourth disease" exists; namely, we have yet to see the occurrence of scarlatiniform rubella, as generally understood, fail to protect from an attack of morbilliform rubella, or *vice versa.* The writer thinks that the existing evidence in support of the generally accepted view is strong.

Ophthalmia Neonatorum.—Reynolds Wilson gives the following summary of the treatment of this affection: (1) The antepartum care of the birth canal; (2) The scrupulous cleansing of the lids following expulsion of the head, and constantly thereafter in suspicious cases; (3) The non-invasion of the palpebral sac by separation of the lids before the appearance of typical discharge; (4) Prompt and absolute isolation upon the appearance of conclusive signs of specific inflammation; (5) Thorough and systematic irrigation; (6) Astringent application of silver nitrate in cases of prolonged suppuration. In conclusion, as an important adjunct to local treatment, attention should be given to the general condition of the child in cases of debility and malnutrition. The measures directed toward the care of the infant are comprised in cod-liver oil inunctions, small doses of whiskey internally, and breast feeding. At the same time the mother should receive some form of tonic treatment.

British Medical Journal, April 5, 1902.

The Causation of Death During the Administration of Chloroform.—E. H. Embley states that chloroform has an immediate and progressively paralytic effect upon the heart muscle. There is no preliminary period of stimulation. There is no abrupt change in the rate or efficiency of the heart. Heart muscle is very sensitive to the poisonous effect of chloroform—a tension of chloroform in blood corresponding to 0.8 per cent. chloroform vapor in the air inhaled kills the isolated mammalian heart in sixteen minutes. In the administration of chloroform by inhalation to the intact animal, the vapor tension of chloroform in the blood only slowly reaches that of the inspired air.

Presence of a Tooth in the Lung.—William T. Gardner reports this case. His patient was a woman, aged twenty-nine years. She was troubled with a very irritable cough, which was constant day and night. No treatment relieved it. She had recently had an attack of pleurisy. She had a sharp hemorrhage and the sputum was bloody, although no tubercle bacilli were ever found in it. Her temperature was that of a typical phthisical case. After some months a very careful inquiry into her previous history discovered that she had within that year had nearly all of her teeth extracted under chloroform. The writer became convinced that she had swallowed a tooth at this time. The Röntgen rays failed to discover any foreign body in the lungs. Several months afterwards the patient coughed up a ragged crown of a tooth, and since that time her symptoms have gradually improved.

A Contribution to the Study of the Presence and Formation of Agglutinins in the Blood.—M. Armand Ruffer and M. Crendiropoulo conclude that: (1) The cultures of a microbe freed from that microbe by filtration, dialysis, or centrifugalization have a distinct, though feeble, agglutinating effect on that particular microbe. The age of the culture and the constitution of the medium are important factors in determining the quantity of agglutinins present in such cultures; (2) The red blood corpuscles of non-immunized and immunized animals contain no trace of agglutinins; (3) On the other hand, the polynuclear leucocytes of non-immunized animals always possess an agglutinating power greater than, or more rarely equal to, that of the serum. They may therefore be rightly considered as the producers, or, at any rate, the carriers, of the agglutinins; (4) In immunized animals the specific agglutinins appear in the polynuclear leucocytes, and are therefore probably formed in them. The quantity of agglutinins begins to increase thirty to forty-eight hours after the injection, and goes on increasing up to the tenth day or thereabout; they then passed into the serum, the agglutinating power of which increases correspondingly; (5) The formation of specific agglutinins in polynuclear leucocytes and in the serum is

[illegible]

The Diagnostic Value of the Variations in the Leucocytes and Other Blood Changes in Typhoid and Malarial Remittent Fevers Respectively.—[illegible] R[illegible] [illegible] An increase of the lymphocytes [illegible] points to typhoid as against malarial fever. [illegible] of great value when parasites are absent from the blood. The presence of [illegible] in any number, [illegible] points to malaria as against typhoid fever. A large degree of anæmia, such as a reduction of the red corpuscles to [illegible] per c.mm., is much more frequently met with in malarial than in typhoid fever. A very great reduction in the total leucocyte count, such as to below 2,000 per c.mm., is much more frequently met with in malarial than in typhoid fever, while the proportion of white to red corpuscles in malaria is not infrequently less than 1 to 3,000, which is rare in typhoid fever. Leucocytosis can be detected by the presence of a great excess of white corpuscles, upwards of 80 per cent. of which are polynuclears, in a stained blood film, and is often of service in excluding malaria in intermittent fever due to liver abscess or other local inflammation.

Deutsche medizinische Wochenschrift, March 20, 1902.

Charcoal as a Substitute for Iodoform.—Arthur Frommer does not think that charcoal is an efficient substitute for iodoform in the local treatment of tuberculous bone and joint lesions. Frankel has thought that iodoform thus used acts chiefly as a mechanical irritant, and that, for this reason, equally good results could be obtained by the employment of charcoal. Following the injection of charcoal a painful swelling of the affected region supervenes, resulting in a more or less extensive necrosis, which is accompanied by fever and continues for two or three weeks. The injection of charcoal-glycerin emulsions produces the same result. The same is never observed after iodoform injections. The difference between these results and those obtained by Frankel is probably due to the fact that his researches were made upon non-tuberculous animals, and the injections were made into healthy tissue. It is certain that charcoal is much inferior to iodoform in the treatment of tuberculous lesions. The use of non-sterile iodoform-glycerin emulsions gives better local and general results than the use of similar sterile preparations. The infective danger of injections of such non-sterile emulsions is not to be considered. In 1,000 such injections Frommer has never produced secondary infection. Following these injections iodine is excreted in the urine for from two to three weeks. This shows that its action is not only local but general. Indeed, the general condition is always benefited by this treatment. Sterilized iodoform injections are not followed by such extended excretion of iodine in the urine.

Iodophilia.—Siegfried Kaminer, as the result of experimental work, regards the so-called iodine reaction of the leucocytes as due to a toxæmia. It is never present under normal conditions. The leucocytes of guinea-pigs and rabbits give this reaction if the animals are inoculated with virulent cultures of streptococcus, staphylococcus, pneumococcus, diphtheria bacillus, typhoid bacillus, anthrax bacillus, colon bacillus, the bacillus pyocyaneus, and Friedländer's bacillus. The bacillus of hog cholera does not produce the reaction. The reaction is also produced by the inoculation of the toxins of these micro-organisms. While diphtheria toxin produces the reaction, tetanus toxin fails to do so. The reaction produced by these toxins is of three grades of intensity: (1) A diffuse brown staining of the protoplasm of the leucocytes; (2) A granular red-brown staining of the protoplasm of the leucocytes; (3) A complete [illegible] of the protoplasm of the leucocytes with the presence of large reddish-brown granules. Animals immunized to diphtheria with diphtheria antiserum, and subsequently inoculated with diphtheria toxin do not show the reaction. The inoculation of ricin and abrin also produces the reaction. The subcutaneous and intravenous inoculation of rabbits with glanders and tubercle bacilli does not produce the reaction. This is, however, readily accomplished by the feeding of tubercle bacilli or the intraperitoneal inoculation of glanders bacilli. The intraperitoneal inoculation [illegible]

[illegible]

Tuberculosis Verrucosa Cutis.—Max Joseph and Gottfried Trautmann [illegible] [illegible] butchers [illegible] butchers [illegible] tuberculous animals. However, [illegible] patients worked in the same slaughter-house, of whom 150 were exposed to tuberculous infection. It is evident, therefore, that a very small proportion of those exposed developed the disease. It should be remembered, however, that other forms of tuberculosis might have been present in some of the other 1[illegible]. The largest proportion of those who suffered from tuberculosis verrucosa cutis were cabinetmakers. The frequency of the disease among them is to be explained by the great liability of their hands to injury. In these, also, the human source of the contagion is the most probable. Of the eight butchers above mentioned, four were also exposed to human infection. From these observations it is apparent that the infection of man by bovine tuberculosis is rare, nevertheless its possibility cannot be denied. In the treatment of tuberculosis verrucosa cutis the local use of a 30 per cent. resorcin paste is to be especially recommended. It is caustic in action, but elective, acting principally upon the tuberculous tissue.

Münchener medizinische Wochenschrift, March 25, 1902.

Vital Properties of Maternal and Fœtal Serum.—Josef Halban and Karl Landsteiner, as the result of comparative studies, show that the vital properties of active maternal serum are more marked than those of active fœtal serum. This applies to its hæmolytic, agglutinating, bactericidal, anti-fermentative (antitryptic), antitoxic, and precipitating properties. The human serum examined, if added in excess, impairs the intensity of the agglutination and precipitation. The precipitation is also lessened by the excessive addition of precipitating immune serum. It is certain that active fœtal serum is of the same chemical composition as active maternal serum, but that the active principles are present in the former in reduced quantity. This explains the slight resistence of the new-born to various infections. Further researches are required in order to ascertain at what period of extra-uterine life the vital properties of the serum are fully developed.

Berliner klinische Wochenschrift, March 24, 1902.

Serum Diagnosis of Pulmonary Tuberculosis.—Francesco De Grazia, as the result of clinical and experimental research, finds that cultures of the bacillus tuberculosis are agglutinated not only by the serum of tuberculous individuals but also by the serum of those suffering with other infections. Frequently also the same result is produced by the serum of perfectly healthy persons. Furthermore, the serum of tuberculous patients energetically agglutinates cultures of various other micro-organisms, such as the staphylococcus pyogenes aureus, typhoid, diphtheria, cholera, and colon bacilli. It is not possible, therefore, to regard the agglutination reaction as specific. No constant relation exists between the intensity of the reaction and the stage of the tuberculous process. In the later stages it may be very marked and in the early stages very slight. The reverse, however, frequently occurs. Dead as well as living tubercle bacilli are thus agglutinated, but with the former the process is much slower than with the latter.

French and Italian Journals.

Chronic Parenchymatous Metritis.—Armand Siredey urges general hygienic treatment as well as the use of local measures in this affection. Congestive tendencies are to be averted by a simple non-stimulating diet; and by securing free catharsis. Over-fatigue is to be avoided; rubbing and hydrotherapy prescribed. Acute congestive attacks are to be treated by rest in bed, scarification of the cervix, glycerin tampons, etc. Intra-uterine treatment is to be very cautiously used, if at all. Curettage is valueless. Instead of the routine hot vaginal douches it is better to give slow, prolonged irrigations of four to five liters of water at 104° F. two or three times a day. When there is great pain, it is better to replace the water by a decoction of poppy and marshmallow roots, with some non-irritating antiseptic, as boric acid.—*La Gynécologie, February*, 1902.

A Case of Acute Yellow Atrophy of the Liver.—The points of interest in the case reported by Tito Carbone are: (1) That it occurred in a boy of twelve years. The affection is rare in childhood. Death occurred in ten days; (2) There were signs of cirrhosis preceding the atrophy. Its course was latent, and its existence was discovered at the autopsy; (3) The mesenteric glands were found in a condition of degeneration and necrosis, which would seem to bear out the theory that acute atrophy of the liver is due to the absorption of toxic substances from the digestive tract.—*La Riforma Medica, March* 11 *and* 12, 1902.

Cyst of the Superior Maxilla.—Maass reports the case of a boy, twelve years old, in whom there developed a tumor filling the canine fossa. This growth appeared eighteen months after the extraction of two teeth for a periostitis at the root. This tumor was covered with a thin, bony plate. Exploratory puncture brought forth the contents, which were composed of leukocytes, cholesterine crystals, and pavement and cubical epithelium. The tumor was a cyst of the root of the tooth, due to a proliferating epithelial formation.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, March 20, 1902.

Fetal Variola Not Secondary to Maternal Disease—Guiseppe Jacontini reports the case of a woman who gave birth to a still-born child, on whom were all the signs of smallpox, of which there had been an epidemic in the neighborhood. The mother had no sign of the disease. The author concludes that there may well be a condition of immunity to certain diseases on the part of a pregnant woman which does not extend to the fœtus. As there was no fever, nor any lesion of the placenta, he holds that the infective substance passed directly from the blood of the mother to that of the fœtus.—*La Riforma Medica, March* 14 *and* 15, 1902.

Garlic in the Treatment of Pulmonary Tuberculosis.—Giulio Cavazzani reports in detail a number of cases in which the administration of garlic absolutely cured cases of undoubted phthisis. The author disclaims any idea of having found a cure for tuberculosis; he simply describes the cases, and asserts that garlic has been of more value to him in treating them than has any other remedy. Three to six grammes a day rapidly reduce the expectoration and finally causes its disappearance. Fever and night sweats cease, cyanosis disappears, and the patient's appetite is greatly improved. All this occurs with great rapidity. The pulmonary symptoms vanish more slowly. Garlic was used of old in bronchitis, and even at the present day is given in the Far East for consumption. It possesses an antiseptic action, and this may, perhaps, be exhibited with especial force in regard to the Koch bacillus.—*Gazzetta Medica Lombarda, February* 16, 1902.

Diagnosis of True and False Intestinal Occlusion in the Course of Pregnancy.—Richelot reports several observations he has made. The first case was a woman of twenty-eight years, pregnant for six months, who exhibited symptoms of intestinal occlusion. Two baths, however, improved her condition and cure followed an electrical bath. The second case was that of a woman whose symptoms simulated those of appendicitis with peritoneal infection. This condition had been precipitated by a fall which had broken her leg. Laparotomy revealed an intact appendix, but the small intestine was empty, retracted, discolored, and bent on itself. This patient was delivered of a dead infant. and the same evening the bowels were evacuated. In this case it was only a nervous affection that had resembled occlusion. The writer calls attention to the necessity in such cases of not only considering the local symptoms, but also of considering the temperament of the patient, especially from the arthritic point of view.—*La Presse Médicale*, March 19, 1902.

Dietetic Treatment of Gastric Catarrh.—Ewald declares that the first indication in this trouble is lavage of the stomach. It will depend upon circumstances whether the morning or evening is the best time. As a rule, the patient prefers the evening, as then sleep is not disturbed. Lavage not only removes the products of fermentation, but also a large number of microorganisms. The favorable effects are increased by using an antiseptic. The functions of the intestine must be regulated. Constipation is the rule in these cases. These patients should never completely satisfy the appetite. Whatever is taken for drink should be lukewarm—neither hot nor cold. The water taken should be pure. Mastication should be thorough. The white meats, fowl and game, are more easy of digestion than beef, mutton or pork. Eggs are not always well tolerated. All irritating foods should be avoided, such as those containing acetic acid, spices, alcohol and rich sauces. Carbohydrates are not well borne. The milk diet is excellent for these cases, but the total quantity necessary is so large that when it is taken in small quantities at a time the patient becomes very weary of the treatment.—*Journal de Médecine de Paris*, March 16, 1902.

Removal of Abdominal Fat in Cases of Large Abdomen.—Pousson speaks of the troubles incident to fatty development of the abdominal wall. Besides the annoying deformity, there very often occurs an obstinate and painful erythema and eczema, under the folds of superfluous flesh which fall down over the hips. To this is added a predisposition to ventral hernia and enteroptosis, for the aponeuroses finally give way under the continuous strain and become distended and relaxed. The writer describes an operation that he has devised for this affection. He relates the case of a woman of forty years, who presented herself for operation for an enormous umbilical hernia. The abdomen was very large and lax, and there was present a painful erythema. After finishing the operation for hernia the writer proceeded at the same time to relieve the abdomen of a part of its superfluous fat. A curved incision was made from one iliac spine to the other with the concavity turned toward the umbilicus. A second incision was then made with the same points for its extremities, but with the middle point about the width of a hand below the first. The fatty tissues thus circumscribed were removed down to the aponeurosis. The two borders of this huge breach were then sutured together. There was union by first intention, and the patient was cured in about fifteen days. The abdomen was firm, and at last reports the result was still most satisfactory.—*Gazette Hebdomadaire des Sciences Médicales*, March 16, 1902.

Rachitis in Relation to Artificial Feeding.—M. G. Variot has spent much time on this subject, and he has come to the conclusion that, aside from mother's milk, which nothing can perfectly replace, the use of sterilized milk is almost as safe as a wet nurse. Mother's milk is, without any doubt, superior to that of animals, but, practically, when the mother is incapable of nursing the child, there are so many possible objections to a wet-nurse that the writer advises the use of sterilized milk for a normal infant. He reserves the wet-nurse as the last resort, in case the child does not thrive on the other treatment.—*La Tribune Médicale*, March 26, 1902.

Transplantation of Sarcoma.—Mayet reports the post-mortem findings in a white rat on the fourth of March. in which had been inserted on the twenty-ninth of November a bit of malignant sarcoma. The point of injection was surrounded by a small cyst hanging from the great omentum. About this primary focus were vegetations which had reached the size of the initial growth. In the great omentum and in the gastrohepatic omentum were secondary growths, four or five in number, in the form of white spherical tumors, and of the size of small peas. Near the primary growth was a very vascular tumor, red, pedunculated, and a little smaller than the others. On the surface of the small intestine were several flattened ovoid growths, three or four millimeters in diameter.—*Lyon Médical*, March 23, 1902.

Hydatid Cysts of the Neck.—Léon Thévenot declares that hydatid cysts of the neck are a very rare affection. As to the etiology, sex seems to have no influence. The affection often occurs in children, but it is between the ages of twenty and thirty years that it is found most frequently. The infection generally comes from animals, and it is the dog that is ordinarily accused as being the source from which the malady is transmitted. The echinococcus, aside from those cases in which it is introduced into the system through a wound of the skin, generally enters through the digestive tube. It is often stopped in its course by the liver, though it may pass out into the general circulation and be arrested in the lungs or even pass still further. This cyst develops so slowly and insidiously that it is only by its volume that it is at last detected. If intervention is early, the prognosis is benign. Otherwise it may open itself into neighboring organs, or become adherent, and its removal will then be made very difficult. The operation may consist of simple incision or of total or partial extirpation of the wall. The former is very simple, but is open to the liability of recurrence. The latter is sometimes difficult. If suppuration has begun, treatment consists of incision and drainage after evacuation of the abscess.—*Gazette des Hôpitaux Civils et Militaires*, March 22, 1902.

American Journal of the Medical Sciences, April, 1902

Primary Tuberculosis of the Liver.—Louis Frank believes that primary tuberculosis of the liver [illegible] may occur. The infection must take place by way of the intestine and the portal circulation, the bacilli finding entrance through an ulcer in the bowel and leaving no trace of the place of entrance into the body. Tuberculosis of the liver may imitate the other abdominal viscera and also the peritoneum secondarily, and the present case also showed a great increase of the connective tissue in the liver [illegible] hepatitis. The disease results fatally [illegible].

Localization of the Mental Faculties in the Left Prefrontal Lobe.—Charles Phelps, from his work on the subject, makes the following generalizations: (1) In every instance but one of the cases studied in which [illegible] was [illegible] or impaired, and the mental faculties were not perverted by general delirium, laceration [illegible] the left frontal lobe was attended by default of intellectual control; the lesion was usually, if not always, of the prefrontal region, and implicated either its superior or inferior surface. Subcortical disintegration or deep or extensive laceration of the cortex was especially characterized by abrogation of mental power, and [illegible] laceration by aberration in its manifestations. (2) In every instance in which laceration was confined to the right lobe, the mental faculties were unaffected except as they were obscured by stupor or delirium occasioned by coincident general lesion. (3) Compression or contusion of the left lobe only exceptionally produced specific intellectual disturbance.

Albuminous Expectoration Following Thoracocentesis.—David Riesman concludes that (1) Albuminous expectoration is a very rare complication of thoracentesis. It is usually serious, and sometimes fatal. (2) It consists in the expectoration of a viscid albuminous fluid closely resembling the fluid of serous effusion. (3) The condition is best explained on the basis of an intense congestion and oedema of the lungs (congestion by recoil). (4) The principal cause seems to be either too rapid or too great a withdrawal of fluid. (5) Serious cardiac disease and morbid conditions of the opposite lung, hindering expansion, are predisposing causes. (6) Under all circumstances, but particularly when these complications exist, aspiration should be performed slowly. If the effusion is large, the amount withdrawn at any one time should be moderate. (7) In some cases it may be wise to perform several tappings, drawing off a small quantity each time. (8) The treatment consists in counter irritation, venesection, and artificial respiration, together with the use of morphine if the cough is severe.

On the Association of Stone and Tumor of the Urinary Bladder, with Report of a Case.—Edward C. Rosenow declares that, contrary to the views of some authorities, an etiological relationship between calculus and tumor is not to be denied altogether, and calculus seems to favor the development of tumor in a larger percentage of cases than tumor favors the development of stone. In over half of the cases which the writer reviews, it appears that the stone was primary in point of time. Inflammation of the urinary bladder resulting from irritation other than that produced by a calculus has been found to cause an increased liability to new growths, and it is therefore permissible to conclude that the mechanical irritation from a calculus may have the same effect. Tumor of the urinary bladder uncomplicated by stone occurs more frequently in the lower segment. In cases of calculus the anterior wall is nearly twice as often the seat of the tumor as the posterior wall. Both calculus and tumor occur more frequently in the male sex, and nearly at the same age. In from 90 to 95 per cent. of primary carcinoma of the gall-bladder biliary calculi are present, so analogy would lead us to expect a somewhat similar relation between stone and tumor in the urinary bladder.

An Experimental Study of the Effects of Change of Color upon Pigment Bacteria.—Charles A. Oliver concludes that color-changes, both of kind and intensity, take place in and around many chromogenic bacteria when such microorganisms are placed under different color conditions. Rehabilitation of chromogen bacteria into old color environments, after having later obtained a new color-value under any particular color-condition, is quite frequently accompanied, sooner or later, with a return of the germ's color-equivalent to that which it primarily held while in its original situation. Differences of color-conditions in pigment-bacteria most probably signify in part relative changes in the various methods of obtaining sustenance, peculiarities in the kinds and the ratios of foodstuffs, and irregularities in the character of resulting excreta, each species of color-bacterium exhibiting its chromogenic change in a typical and relevant manner, a behavior that has its determining effect upon the very [illegible] of the germ itself. The naming of bacteria by specific [illegible] is only of value when the actual habitat of the microorganism is understood. It is most certain that all color-changes of true [illegible] type in living animal or vegetable forms are expressions of [illegible] [illegible] that taking place in and around the organism.

Annals of Surgery, April, 1902

Graves's Disease Treated by Ligation of All Four Thyroid Arteries.—R. H. M. Dawbarn reports the case of a woman of [illegible] years presenting all the classical signs of Graves's disease. The goiter was not very large, but on account of its three lobes, severe pressure was exerted on the trachea. Excision was not thought advisable. If [illegible] it leaves [illegible] of [illegible] death [illegible] to quickly follow the operation, and there is danger of subsequent [illegible]. So all four thyroid arteries were ligated. Primary union resulted, and the dressings were removed on the fifth day. The neck, which before operation measured [illegible] inches, [illegible] by [illegible] in a few days. Other symptoms were improved. In addition the patient was placed upon the dietary treatment which has been so strongly advocated by W. H. Thomson, that is, the avoidance of highly nitrogenous food, especially meats, and the use of milk in various forms and [illegible], combined with the persistent administration of [illegible] such as [illegible] bismuth, and an occasional mercurial purge.

An Experimental and Clinical Research on the Temporary Closure of the Carotid Arteries.—From experimental researches on dogs, and from the results of eighteen operations on patients suffering from various tumors about the head and neck, George Crile presents the following clinical summary: Closure was effected by the use of a clamp inserted through a very small incision. One or more carotid arteries were closed in eighteen patients. Both common carotids were closed in [illegible]; one common carotid in two; one external carotid in three. In all there were twenty-eight closures of individual vessels. The ages of the patients ranged from seven months to sixty-[illegible] years. There were no deaths attributable to the temporary closure of the arteries. In every instance the circulation was resumed immediately upon releasing the clamps. There were no appreciable late effects upon the vessel wall at the point of clamping, and none upon the circulation in the closed arteries and their branches. There were no later cerebral effects. Less anesthetic was necessary with closed arteries, especially in the cases in which common carotids were closed. In the latter case there may be embarrassed respiration, especially later. The complete or partial release of one or both carotids gave material and immediate assistance to the respiration. The operating time was much diminished, since the field of operation was quite free from blood. The amount of blood loss was strikingly less, as was also the difficulty in keeping blood from the respiratory tract.

Prostatectomy by the Perineal Route.—Parker Syms describes a bladder retractor which has served a useful purpose in the operation named in the title. It consists of a rubber tube of a caliber of 35 French scale, having a rubber bulb attached to one end, which can be dilated when introduced into the bladder. With the aid of this instrument the operation is performed as follows: The patient is placed in the lithotomy position under ether narcosis; a median perineal section is made, extending from the bulbous portion of the urethra as far back as is safe without injuring the rectum. The membranous urethra is exposed by dissecting backward until the tip of the prostate is reached; an opening about an inch in length is made in the membranous urethra, a staff having been introduced into the bladder; the bladder is now carefully irrigated, the prostatic urethra is dilated, and then the rubber retractor, collapsed, is introduced through this opening in the membranous urethra so that the bulb is well within the bladder; then this bulb is dilated to a diameter of two and a half inches by injecting two and a half ounces of water through the tube by means of a piston syringe; the tube is then clamped to prevent the escape of the water; firm traction is made on this tube, and then it is turned well up over the perineum and held there by an assistant; it will not be in the operator's way, and it will be found that this traction holds the neck of the bladder and the prostate from receding, and gives the requisite fixation to enable one to enucleate the diseased lobes. Now the capsule of the gland is entered and the lobes are enucleated by the index-finger; in this enucleation the prostatic urethra will be torn through quite frequently; Syms has done this in several instances, but without prejudicing the final result of the case. In some instances the enucleation will be accomplished with comparative facility, though it must not be assumed that prostatectomy is ever an easy operation.

Stated Meeting, Held April 3, 1902.

ROBERT F. WEIR, M.D., PRESIDENT.

The Modern Treatment of Fractures of the Lower End of the Radius as It Is Dictated by the Relations Shown by the Röntgen Rays.—Dr. CARL BECK read a paper with this title. He said that it had been found that the anatomical aspects of the various forms of fracture at the lower end of the radius differ more than in the case of any other fracture. In the first place, the question of whether or not the fracture is extra or intra-capsular was of great importance. A solution of continuity about one inch or one inch and a half above the carpal epiphysis causes the "silver fork" deformity in the majority of cases, but there are still many cases which do not present this characteristic appearance first described by Colles. In classifying the various fractures of the lower end of the radius one should distinguish the following: (1) The epiphyseal fracture; (2) Fissure of the carpal end of the radius; (3) Complete fracture; (4) Incomplete fracture; (5) Fracture of the carpal end of the radius with fracture of the styloid process of the ulna; (6) Associated fracture of the lower end of the ulna, and (7) Fracture of the carpal end of the radius with fissure or fracture of the scaphoid bone. Just as the healing of wounds of the soft parts by first intention required careful adaptation of the wound surfaces, so in fractures a quick and perfect result occurred only under the same conditions. Fortunately, at the present time this could be done through the guidance of the Röntgen rays. In cases of fissure of the carpal end of the radius a simple band around the wrist would insure comfort and sufficient restriction of motion, at the same time allowing sufficient motion of the fingers and hand to prevent adhesions of the tendons. The wrist should be carried in a sling with the ulnar side of the hand on the edge of the sling, and the patient should be instructed to move the fingers frequently as in playing the piano. A good plan was to have the patient carry some marbles in the pocket, and from time to time roll them with the fingers in the palm of the hand. In the majority of cases of fracture of the lower end of the radius associated with deformity the direction of the displacement would be found toward the ulna. He found no dressing better for these cases than plaster of paris. If the direction of the displacement were slightly upward and outward the plaster-of-paris splint should embrace the thumb, and the hand should be moderately flexed. Having applied the bandage, the Röntgen rays should be called into requisition to determine whether or not the fracture had been properly reduced. This fluoroscopic examination should be made not only antero-posteriorly, but also laterally. In the Y-shaped variety one fragment was usually displaced towards the ulna and the other outward. After reduction the fragments should be kept apart and in place by pressure made in the interosseous space by means of a piece of rubber tubing, held in position by a strip of adhesive plaster, passing partly around the forearm. Fracture of the lower end of the radius, associated with fracture of the styloid process of the ulna, was not uncommon, having constituted about 26 per cent. in his experience. This fracture should be put up in plaster of paris in moderate abduction. The fracturing off of small pieces of bone was often mistaken for contusion or sprain. It was not surprising that patients of this class should become rebellious when treated by massage.

The Common Error in Treating Fractures of the Lower End of the Radius.—Dr. J. B. ROBERTS of Philadelphia was the author of this paper. He said that in the fracture under discussion the reduction of the fracture could rarely be effected without the exercise of considerable force. Students were seldom taught that this fracture was one eminently needing to be "set," and that this process required nearly all of the force that could be exerted with the two hands. It should be remembered that the palmar surface of the radius is concave, while the dorsal surface is nearly flat, and that these curves should be restored by the process of "setting" the fracture. The method was not so important as the exercise of the requisite amount of force. There is a slight elevation on the dorsal aspect of the radius, just at the point where the extensor tendons run in grooves. The surgeon must force forward the lower fragment which has been thrust backward by the force of the injury. Reduction might be effected without anæsthesia if the surgeon were quick and bold, though the pain for the moment is very severe. When the fracture had gone unreduced for several weeks it was better to employ general anæsthesia. This should always be employed if the surgeon were so afraid of giving pain that he was likely to slight his work. Pressure with the surgeon's finger tips would usually show him if the normal curves of the bony surfaces had been restored. When the fracture had been thus reduced the patient would hardly have any further need for the surgeon. A patient who could be trusted not to subject the forearm to muscular strain and not to fall upon it would probably do well if he only wore a sling for three weeks. It is usually safer, however, to apply a straight posterior splint, extending from the middle of the forearm to the middle of the metacarpus. In many cases a wristlet of adhesive plaster, three or four inches wide, would be found a simple and efficient dressing for this fracture. If these simple suggestions were heeded no fracture would be so welcome as that of the lower end of the radius because of the speedy convalescence and the very satisfactory results.

The Treatment at the Vanderbilt Clinic.—Dr. E. M. FOOTE read this paper. He said that most of the surgeons at this clinic were of the opinion that an anæsthetic was not necessary except in complicated cases, or in very nervous patients, but personally he was strongly in favor of using an anæsthetic, believing that this had very much to do with securing a good result. He also thought the Röntgen rays were most useful in guiding the treatment of this fracture, but, as a rule, four *x*-ray pictures would be required, two before and two after the dressing, and as this involved an expense of $25 to $40, the method was hardly available among people of slender means. No uniform splint was employed at this clinic, the splint being adapted to the individual case. While he believed that the *x*-ray was most useful and important, the clinical diagnosis should not be neglected, and undue reliance be placed upon the *x*-ray diagnosis.

Treatment at the Hudson Street Hospital.—Dr. F. L. TAYLOR read this paper. He said that in many cases traction alone without an anæsthetic would suffice to effect reduction of the fracture. In a few cases it might be necessary to overextend, and then sharply flex, the part. When the bony surfaces were obscured by swelling a fluoroscopic examination was made. When the radius and ulna were separated by soft structures, complete reduction might be impossible, and in such cases a very serviceable, though somewhat unsightly, wrist would result in time. At this hospital the fracture was put up in anterior and posterior molded splints, in a partially prone position, with the wrist slightly extended. The splints extend from the junction of the middle and upper thirds of the forearm to the middle of the palm and of the dorsum, respectively. The parts having been smeared with vaseline, the plaster splints are applied directly to the skin, and are removed until the end of the third or fourth week. In children and in inebriates the splint is kept on a week longer than necessary, to avoid refracture. This form of splint allowed of the radius and ulna being held together, thus preventing the marked spreading of the joint so often seen; it allowed of carrying out frequent [illegible] and [illegible] the patient to put the arm through [illegible]. In old and neglected cases an improvement could sometimes be effected by refracture under anesthesia.

Treatment at the New York Hospital.—Dr B T Tilton presented this paper. He did not think enough stress had been laid upon the importance of using anæsthesia in order to insure thorough reduction. Many of the cases coming to the New York Hospital were not perfectly fresh, and hence an anesthetic was usually required. When there was not tendency to impaction of the fragments, anesthesia seemed to him imperative. He had usually used the ordinary wooden splint, padded in three places, viz: over the dorsum of the arm, on the palmar surface, and on the lower end of the ulna. He only made use of the plaster-of-paris splints when there was a tendency to displacement. The after-treatment seemed to him of much importance in order to insure a good functional result. He was accustomed to resort very early to finger movements, especially in persons over forty. At the end of the first week these movements were begun and the splint was gradually shortened, so as to facilitate this. The fingers were particularly to become stiff if kept straight. He had seen results which were good at the end of three weeks, yet the removal of the splint at this time had ultimately caused a return of the deformity. He was, therefore, opposed to the early removal of the splint.

Treatment at the Roosevelt Hospital.—Dr W C Clarke said that it was customary at this hospital to make the first examination under ether or gas anæsthesia. After reduction of the fracture, a molded splint was used anteriorly and posteriorly, as it was found to be much more comfortable than the straight wooden splint. The splints reach from near the elbow to the middle of the fingers. In young persons the hand was put up straight, but in persons over thirty years of age the hand was hyperextended on the forearm. At the end of the first week the splint was shortened to the base of the fingers, and at the end of the second week it was shortened up to the wrist. After three weeks the splint was shortened sufficiently to allow of pronation and supination. The patient then received massage daily, a part of the treatment which apparently did a great deal toward securing a good functional result. Examination under anesthesia had been found so satisfactory that the x-ray had been used only to a limited extent.

Massage and Hot Air Useful.—Dr J P Fiske spoke in favor of the more extended use of the Röntgen rays. He thought anesthesia should be employed in all cases of Colles' fracture, and that if this were done as a routine measure there would be fewer poor results. The introduction of massage had greatly improved the results. The employment of dry heat at 150° in cases of fracture near the large joints, especially in persons over forty years of age, had been demonstrated to be exceedingly useful and it insured an earlier return of function. Only when there was a tendency to displacement should the splint be applied as long as was necessary to secure bony union.

Dr George R Fowler of Brooklyn said that he had hoped to hear more said about the diagnosis of the more obscure cases of fracture of the lower end of the radius, aside from the use of the Röntgen rays. A large number of persons suffering from this injury were unable to pay for the use of the x-rays, and hence it was important to discriminate in other ways between simple contusion and sprain and actual fracture of the base of the radius. He had hoped to hear something said about the method of determining this by shortening of the radius as compared with the ulna and the elevation of the styloid process of the radius to the same level as that of the ulna. In his opinion this was a fairly good guide if the case were seen sufficiently early. A deformity which was not appreciable without the use of the Röntgen rays was not likely to give rise ultimately to any great impairment of function. In the cases referred to he had been in the habit of removing a portion of the lower end of the ulna, and had succeeded in lessening or entirely overcoming deformity, and, at the same time, restoring the hand to a condition of comparative usefulness.

Dr Stephen Smith said that, probably, no other fracture had given rise to such a large variety of methods of treatment, yet it was an interesting fact that the man who first described this fracture stated that he uniformly cured his cases without the slightest deformity, and secured a perfect functional result by a very simple method. That method consisted in putting a transverse pad on the prominence on the dorsal surface and holding it in place by a bandage, and in putting over this a tin splint and another bandage. The speaker said that, according to his own experience, many cases could be quickly reduced, but would quickly return if traction were not kept up. In other cases, no matter how much traction were made, proper reduction could not be effected. The dressing he had ordinarily employed he believed he had first seen used in the New York Hospital. It consisted of two wooden splints, extending to the bases of the metacarpal bones posteriorly, and to the base of the thumb on the palmar side. These two splints were kept in place by strips of adhesive plaster, so applied as to give support to the ulna and at the same time hold the splints in position, and leave the site of the fracture entirely exposed. Dr Smith said that he recalled the case of one hospital patient who disappeared after the first application of this dressing, and did not return for four months, yet at this time the dressing was found to be in perfect position. He had advocated the use of this dressing when teaching students, and had subsequently learned from many of them that they had found it most serviceable in their practice.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY

Stated Meeting, Held March 27, 1902

James N West, M D, Chairman

A Clinical Report Relating to Hemorrhage Persisting Notwithstanding Curettage; Also Secondary Hemorrhage Following Abdominal Section.—Dr Egbert H. Grandin read this paper. (See page 571.)

Dr H J Boldt recalled an instance of uterine hemorrhage, observed some years ago, in which the source of the hemorrhage was found to be a cavernous angioma. He agreed with the reader of the paper that in almost all instances one could be reasonably certain regarding the existence of a secondary hemorrhage, and also that the diagnosis could be cleared up by exploration through the culdesac. Some years ago he had stated, in a discussion on abdominal surgery, his opinion that nine-tenths of the deaths occurring after abdominal operations, and ascribed to shock, were really due to other causes.

Dr William S Stone reported on the examination of the vascular thickening found near the horn of the uterus in one of Dr Grandin's cases. Microscopical examinations showed nothing more than a hypertrophic endometritis and a recent exudative inflammation in the stroma.

Dr A Brothers spoke of a case of uterine hemorrhage in which curettage and amputation of the uterus had failed to check the bleeding. He had then tried vaporization of the uterus with a like result. He had accordingly removed the uterus and found hypertrophy of the muscular structure and what the pathologist reported to be incipient carcinoma. In another case, after repeated curettage had failed to control the bleeding, he had removed the uterus and found a deciduoma malignum. In still another case curettage and vaporization with superheated steam failed to control the bleeding, and after removal of the uterus the pathologist was unable to find any cause for the hemorrhage. He had had two cases of secondary hemorrhage, both following the use of a mass ligature, and in both he had reopened the abdomen as advised by the reader of the paper.

Dr. H. N. Vineberg said that secondary hemorrhage in the majority of cases was primary hemorrhage that had not been arrested—in other words, a small bleeding spot was frequently left behind uncontrolled, in the belief that it was of no importance. In his opinion, the differential diagnosis between internal hemorrhage and shock was not an easy matter. Many nervous women, after recovering from the stimulating effect of the ether, develop a rapid pulse, which causes the surgeon some anxiety for a time. When internal hemorrhage was suspected he thought it was better to reopen the abdominal incision. The making of an exploratory incision through the culdesac was not always an easy procedure, because of the formation of adhesions and the consequent danger of opening into the intestine. For this reason he did not agree with Dr. Grandin as to the advisability of making this posterior exploratory incision in cases of suspected hemorrhage.

Dr. Philander A. Harris thought that most of the cases of so-called shock were really examples of hemorrhage. He wished Dr. Grandin would lay down some definite rules for making the differential diagnosis other than by posterior vaginal incision, for, the latter procedure had certain manifest disadvantages. The speaker narrated a case in which twelve hours after the operation the pulse rose from 90 to 130, although the temperature was normal. Two doses of morphia were given without clearing up the diagnosis. Thinking that this rapid pulse without fever indicated internal hemorrhage, he reopened the abdomen, and although at that time the patient's pulse was 150 he was chagrined to find that there was no hemorrhage. The temperature was normal at this time, but began to rise immediately after closing the abdomen, and at the time of the patient's death, twenty-four hours later, the temperature was 105° F. This case was reported to show how, in a case of sepsis, there might be at first a rapid pulse without elevation of temperature, and so might lead to an erroneous diagnosis of internal hemorrhage.

Dr. G. H. Balleray reported two cases in which he felt that if he had reopened the abdomen the patient would have died. It should not be forgotten that a patient may become almost pulseless from shock entirely independent of hemorrhage.

Dr. L. J. Ladinski said that he did not believe it was necessary to make an exploratory incision in order to establish the diagnosis of extrauterine pregnancy, and he declared that the diagnosis could be made as certainly in this affection without such a procedure as in other pelvic diseases. Moreover, operation was indicated in the cases most likely to be mistaken for ectopic gestation. He thought it would be very difficult to make an exact differential diagnosis between hemorrhage and shock, pure and simple, but a very large majority of cases of so-called shock were really due to hemorrhage. Mention was made of the case of an extremely nervous woman who went into such a condition of extreme shock that he had hastily opened the abdomen, but had found absolutely no bleeding. The patient recovered, showing that the case was one of pure shock.

Dr. Grandin said that he had never made the statement that it was necessary to make an exploratory section in order to make the diagnosis of ectopic gestation, although frequently an exploratory vaginal section was indicated in order to make a positive differential diagnosis in the obscure cases. In very nervous and hysterical women the pulse might remain at 140 for several days, but it could be brought down during sleep by the use of morphia. Given the rapid pulse, the gradually, increasing pallor of the mucous membranes, the air hunger, the elevation of the surface temperature of the abdomen and the bulging of the posterior vaginal fornix there could be absolutely no question about the presence of internal hemorrhage. If in such a case morphia were administered the symptoms would be aggravated instead of relieved, as they would be in a case of shock. The great value of the posterior vaginal section was that it enabled the timid and the inexperienced surgeon to establish the diagnosis. He was thoroughly satisfied that he could make an incision into Douglas' culdesac without disturbing the patient and without anæsthesia, and without injuring the bowel determine whether or not hemorrhage was present.

Michel's Mettallic Clamps for Skin Approximation.—Dr. H. J. Boldt exhibited this simple device, which, he said, he had found convenient and useful for skin approximation. The clamps are cheap; can be readily sterilized, and are quickly and accurately applied.

An Improved Tube for Intravenous Infusion.—Dr. Philander A. Harris exhibited the Kelly tube, which he had modified by having several swells made on the shank of the tube, so as to readily accommodate snugly the various sizes of rubber tubing. Of course, a similar device had long been used on rubber hose, but his object was to apply it to the infusion tube, so as to make that instrument available for instant use at any time.

A Retractor for Exposing the Retrouterine Space in Abdominal Section.—Dr. Harris also exhibited a broad metal retractor having a long curve, which made it easy to bring the uterus forward and upward. The handle of the retractor is bent at a right-angle to the shaft of the instrument.

Dr. Ladinski said that this modification of the infusion tube had been suggested several years ago by Dr. Luckett, and that such a tube was now in the market.

Dr. Brooks H. Wells objected to the use of Michel's clamps, on the ground that a subcuticular suture of silkworm gut would answer the same purpose, and it was well not to introduce unnecessary complications or instruments.

A Unique Monster.— Dr. A. Ernest Gallant presented this anencephalic monster. There was an entire absence of one side of the body from the right shoulder down. The left side of the body had swung around so much that the left hip was where the right shoulder should be. There was no brain and cranial bones, though the face was well formed. The diaphragm was absent and the foot had seven toes. Radiographs, taken by Dr. William J. Morton, were exhibited. The monster had been delivered at term by Dr. James A. Campbell after what the midwife called a normal labor. It was the mother's thirteenth pregnancy.

Dr. Brooks H. Wells said that the cause of the monstrosity must have been some injury to the fœtus at a very early stage of its development, which destroyed one-half of the body. He suggested that the monster be called a hemisomus.

Dr. S. Marx said that it was unfortunate that no accurate history of the labor was obtainable, because most of these monsters were born with very little liquor amnii. It was supposed that distortions occur as a result of absence of liquor amnii and the consequent pressure upon the fœtus.

Dr. Wells said that quite a large percentage of monsters are born in connection with the opposite condition, hydramnios. He recalled one case of this kind, in which he had found an entire deficiency of the front part of the fœtus.

Ovarian Cyst Mistaken for Ascites.—Dr. G. H. Balleray exhibited an ovarian cyst removed from a woman who had been admitted to the medical ward of the hospital on the supposition that she was suffering from dropsy. Vomiting was very severe, and he opened the abdomen. This operation revealed a simple cyst of the [illegible] free from adhesions. The vomiting ceased at once, and she made a good recovery. The tumor weighed seventeen pounds.

Vaginal Hysterectomy for Puerperal Sepsis with Microscopic Sections of the Uterus.—Dr. H. J. Boldt reported this case and presented the specimens. The patient, a primipara, had been confined six days previously. According to the statement of her physician, the labor had been tedious and complicated by an adherent placenta, which was detached manually. On the third day after confinement the patient had developed a temperature of 102 to 104° F. The uterus had been irrigated a number of times with a weak bichloride of mercury solution. On the sixth day he had seen her in consultation. The countenance had the expression of one ill with intense septic infection. The pulse was 136 and the temperature 106° F. The abdomen was neither distended nor sensitive to pressure, showing an absence of peritoneal irritation. The uterus was large and boggy, and the cervical canal sufficiently patulous to admit a finger. No placental tissue could be felt in the interior. The parametria were free. There was no odor to the lochia. Dr. Boldt diagnosed septic infection, limited to the uterus. The patient was transported to the hospital the same night, and on arrival there a blood culture was immediately made. An intravenous infusion of 1,000 c.c. of saline solution was given, and subsequently the uterus was irrigated with boric acid solution, and an ice coil placed on the abdomen to reduce the temperature. A chill followed the intravenous infusion, but it was not repeated, and subsequently the temperature declined to 99° F. On the following morning the condition of the woman had markedly improved. The temperature, however, rose again. From this time on she became practically unconscious, and remained so, although the temperature dropped again to 99°. A number of blood cultures, taken at intervals, showed no microorganisms. The local condition still being as it was at the time of the first examination, Dr. Boldt decided to do a hysterectomy. Because of the semi-conscious state of the woman only a few inhalations of nitrous oxide were administered. The uterus was removed in a few minutes, and the patient was put to bed in about the same condition as before operation. During the first twenty-four hours her condition seemed to improve, as was manifested by a better and slower pulse and temporary disappearance of somnolence, but after that she began to sink again, and died on the third day. Unfortunately, an autopsy was not obtained. The microscopic sections of the uterus showed the invasion of streptococci through the mucosa in one place just beyond the boundary line into the muscularis. No other microorganisms were seen in the sections. Dr. Boldt said he had not been able to save any patients ill with bacteremia (the invasion of the circulation by microorganisms), and was therefore still undecided as to the proper treatment of such patients. He had had recently a number of patients desperately ill with septic infection. Blood cultures proved negative. They were treated on the plan outlined by him in a recent paper on puerperal septic infection and all recovered. He could not explain his bad results in the bacteremic patients, when others, notably Prochownick of Hamburg had achieved such good results with hysterectomy. He did not believe that, in view of such testimony, we should absolutely condemn the procedure, unless further accumulated experience should show it to be irrational. Theoretically it did not seem possible for such patients to recover because the blood was a good growth-medium for such microorganisms, and when such a small quantity of blood as was used for a culture already showed their presence, it was to be assumed that a goodly number must be present in the circulation—certainly more than the vitality of the system can overcome, even if the primary source was removed. The organisms in the blood would multiply too rapidly to allow of a good result.

A Large Ovarian Cyst.—Dr. A. Brothers presented an ovarian cyst weighing thirty-eight pounds which he had just removed by operation. The woman had been sent to him by her physician with a diagnosis of ascites, but physical examination at the hospital had led Dr. Brothers to doubt the correctness of this diagnosis. The tumor, which was a monolocular cyst, was removed through a two-inch incision because of the absence of adhesions.

Dr. William S. Stone said that he understood Dr. Boldt to argue that when the streptococci or other microorganisms had reached the general circulation the case was not suitable for operation. It should be remembered that often the infection becomes general, and yet so few bacteria are found in the blood that one may be readily led to infer that no general infection had taken place.

Dr. Boldt replied that when the point of infection was only in the uterus, so far as could be determined by examination, and the infectious elements were already in the blood, then, he thought, the uterus should be removed. He relied upon the blood examination to tell him this.

Further Remarks on Intestinal Anastomosis.—Dr. Frederick Holme Wiggin said that he presented this paper to the Section because operating gynecologists were so apt to wound the bowel that they should be conversant with the methods of repairing such injuries. It was important to remove all thickened intestinal tissue. He had found horsehair the best suture material, as it was elastic and allowed the use of a small needle. He objected to the Murphy button on the ground that the instrument was a foreign body and was occasionally retained, necessitating a second laparotomy, and that the variations in the construction of the button, wholly beyond the control of the surgeon, made this device unreliable and dangerous. Moreover, the caliber of the button easily became clogged with fecal matter. Maunsell's great work was the demonstration that the bowel can be safely united by means of sutures passed through all the coats of the bowel, and that the knots can be placed within the lumen. His method required no mechanical device, and it would have undoubtedly come more into favor had it not happened that the method was brought to the notice of the profession at the time when the simplicity and the ingenuity of the Murphy button had caught the popular fancy. Dr. Wiggin then described his previously published modification and improvement of the Maunsell method of intestinal suture. By this method of suturing any portion of the intestinal tract can be united to any other portion. The mesenteric portions are first united. He had followed a number of these cases for two or three years after the operation and had never found any evidence of constriction of the bowel. Dr. J. Gregory Connell substituted a loop suture for the circular one employed by Dr. Wiggin, a modification of no great practical importance. It should be remembered that hydrogen dioxide could be safely employed for cleansing the peritoneum, that special care must be taken in uniting the mesenteric portions, that the formation of intestinal adhesions may be prevented by leaving behind in the peritoneal cavity a quantity of saline solution before closing the abdominal wound, and that there was ordinarily less danger from closing the abdominal wound than from packing with gauze, and that union of the sutured parts takes only about sixty hours.

Dr. Brooks H. Wells said that it was certainly a great advantage to be able to do an intestinal anastomosis at any time, and with only the instruments that the surgeons might happen to have with him. He had personally had very good results from the use of the O'Hara forceps, the operation being easily performed and the convalescence being exceptionally smooth. This forceps makes it very simple to bring together the two portions of bowel, and a mattress suture of horsehair completes the operation. After the application of the stitches the forceps are drawn out.

Dr. Boldt said that he had recently had a case in which the Murphy button had become obstructed by hard fecal matter, and death had resulted. He would like to know how Dr. Murphy meets this objection.

Dr. Wiggin replied that Dr. Murphy made no effort to answer that objection. He did not think the button was being used very much at the present time. Undoubtedly good results might be obtained with the forceps described by Dr. Wells, but he thought it was rather better to put most of the knots on the inside, because in this way there would be less danger of the formation of intestinal adhesions. It also seemed to him well for the surgeon to accustom himself to dispense, as far as possible, with special devices.

THE PRACTITIONERS' SOCIETY.

One Hundred and Seventieth Regular Meeting, Held on Friday, March 7, 1902.

Joseph D. Bryant, M.D., President, in the Chair.

Remarks Concerning the Practice of Aseptic Surgery.—Dr. Charles McBurney read a paper on this subject. He said that by the term aseptic surgery we mean surgery which is conducted under conditions and with appliances which are as free from germ life as we are able to make them. In the practice of aseptic surgery we assume that every object which can, either directly or indirectly, come in contact with the wound, having been made surgically clean, we may make the wound without sepsis. We assume that wounds made under these conditions will heal without aid other than protection against sepsis, and we discard as utterly unavailing all chemical agents which are intended to hasten or encourage the natural tendency, on the part of the wounded tissues, to repair the damage done them. As far as is possible, with our present knowledge, we cleanse every object which may come in contact with the field of operation by heat, which more nearly perfectly than any other agent sterilizes instruments, ligatures, sponges, towels, dressings and bandages. We cleanse the surface of the patient in the gentlest but most perfect manner, first, with prolonged applications of a simple, non-irritating soap, then with soap and water, which removes all loose material of every description, and we get rid of soap and oily material on the surface of the patient by a final washing with sterile water and ether. We know very well that the skin in its sweat glands and hair follicles is permeated with germs, and for that reason we carefully avoid the use of scrubbing-brushes, caustic soaps and other strong chemical agents, which often break and excoriate the skin, and so afford means for the exit and re-entrance of numerous bacteria, which, if left undisturbed, we know to be harmful.

The skin having been made perfectly clean, a moist sterilized towel will protect it until the moment of operation. The surrounding area of skin, clothing and table is also covered in every direction with sterile material, which should be moist, in order that it may not readily slip and uncover an unsterilized object.

The patient is now prepared for the operation, and there remains to be considered only the living instruments, the hands, which must enter the wound and touch every sterile object about it. The sterilization of the hands has occupied the attention of surgeons and bacteriologists for many years, and while it is possible to temporarily sterilize some hands, if sufficient time and trouble are expended in the process, still the active use of the hands during an operation is accompanied by free exudation from the skin follicles, and by a continuous separation of the epithelium, so that the hand which may begin an operation in a sterile condition cannot be sterile after a few minutes' use. The speaker condemned all use of the naked hand in operations as inconsistent with correct ideas of asepsis. The problem is easily solved by covering the hand with a material which has been boiled and which is impervious to fluids, namely, thin India rubber gloves. The objections which have been made against the use of rubber gloves he regarded as purely theoretical. If the glove fits perfectly, the most delicate objects can be felt with perfect appreciation. As regards the liability to cut or puncture the glove, the careful sergeon is no more likely to do that than he is to commit other gross errors in manipulation.

The forearms, from the wrist to the elbows, should be covered with snug-fitting sleeves made of some sterile material, so that the bare skin of the arms may not come in contact with the wound, instruments, etc. The surgeon and his assistants should be clothed in sterilized gowns or coats. Caps on the head and respirators before the mouth the speaker said he regarded as unnecessary.

In making the wound, knives should be sharp, so that incisions may be clean-cut and not ragged and torn, for the latter condition is accompanied often by the death of minute fragments which favor the development of bacteria. For the same reason, what is called "blunt" dissection is to be deprecated. Especially should delicate tissues like the serous membranes and all those which are low in vitality be very gently handled, that epithelium, upon which so much depends, and minute vessels, which supply nutrition, may not be injured. Hemorrhage should be checked as early as possible, not only to save the blood of the patient and so preserve his general capacity of repair, but also to prevent the formation of small blood-clots in the loose connective tissue, which often give rise to collections of serum, and so creates a condition taxing, more or less, the reparative power. To remove small clots and blood fluid from the field of operation, it should be frequently washed with a 6-10 per cent. hot salt solution, which has been perfectly sterilized. What is called "dry sponging" is not desirable, for by this practice delicate cells are crushed and bruised. Preparations of an antiseptic nature, such as bichloride of mercury, carbolic acid, alcohol, iodoform, etc., are to be absolutely avoided, for if the wound is aseptic they cannot possibly do any good, and they may do positive harm by causing superficial cell injury and so create a condition favorable to germ life. Ligatures to control hemorrhage should be of fine material, so as to leave small knots, and should strangulate as small a bit of tissue only as is essential, and all ligatures should be of absorbable material, like catgut. Hemostasis should be made as complete as possible.

Before concluding his paper Dr. McBurney spoke of the importance of the aseptic handling of septic wounds. Because a wound is already septic the belief is widely entertained that many aseptic precautions may be omitted when operation is called for in such a case. Such a theory is quite erroneous. As regards the activity and virulence of sepsis, we find a great variety in different cases. In some an abundant collection of pus is nearly aseptic, and in others a very slight septic discharge is poisonous in the highest degree when applied to a freshly-exposed tissue. In all cases the addition of fresh septic germs will add to the activity of the sepsis which already exists.

Dr. T. Mitchell Prudden said that it was interesting to note how closely the practical conclusions of Dr. McBurney were in accord with the results derived from laboratory studies on the mechanism through which both immunity from infection and healing are secured. It would seem desirable to avoid the presence of blood-clots and of injured and dead tissue in a wound not only because these, as the speaker had indicated, might favor the development of bacteria, but also because, since the removal of these foreign materials must be effected by the same agencies as are concerned in the destruction of bacteria, they should, as far as possible, be left free for the accomplishment of the latter end. In other words, it may well be true that if the phagocytic capacities of cells be largely drawn upon for the disposal of dead or foreign tissue in a wound, the local capacity of the body to resist the invasion of germs will be proportionately reduced.

The President, Dr. Bryant, said that many of the points raised and upheld by Dr McBurney were of inestimable value in the practice of aseptic surgery. For example, a vigorous rubbing with a stiff brush for the purpose of cleansing the skin is not infrequently followed by free oozing, and in such cases an accumulation of blood is formed which is avoided by the employment of gentler methods. Another important detail is the absolute arrest of bleeding points and the close coaptation of the wound surfaces, in order to avoid dead spaces. Under certain seemingly aseptic conditions, Dr Bryant said, he thought drainage was justifiable, because it must be admitted that even under the most favorable circumstances, suppuration occasionally occurs.

Dr Bryant said he was thoroughly in accord with the views expressed by the reader of the paper regarding the aseptic treatment of septic wounds. There are two reasons why the same amount of care should be exercised in the treatment of a septic wound as of a fresh wound: First, because of the danger of reinfecting a septic wound with other septic germs, and, second, because a lack of the usual precautions in the treatment of septic wounds begets habits of carelessness on the part of the surgeon. In the redressing of wounds, also, the aseptic precautions should be just as absolute as in the operative work, if for no other purpose than to instil proper discipline into the minds of those who are brought into contact with open wounds.

In reply to a question, Dr Bryant said he would advise drainage in a case where he was in doubt as to the proper cleanliness or proper closure of a wound or where he felt that dead spaces might form. The use of a drainage agent is regarded by many as a confession of lack of faith on the part of the surgeon in his own methods, but it should not always be construed in that light, but instead as a determination to be safe rather than sorry in that instance.

Dr McBurney said he looked upon the proper drainage of wounds as a very important aseptic precaution. The application of drainage to a clean and closed wound does not imply a lack of confidence in the methods employed; drainage should be provided for, as it is better that free blood should escape into the dressings, than that it should collect in the wound, and possibly occasionally interfere with aseptic repair while awaiting absorption.

The fact that even serious wounds sometimes heal readily in spite of the contamination from dirty fingers and instruments only shows that nature is both powerful and kind. Such isolated cases do not prove anything, but their influence is unfortunate, as they are apt to lead to habits of carelessness in the treatment of wounds in general.

Dr ANDREW H. SMITH said that Dr McBurney spoke of renewing the drainage as soon as the gauze became saturated. This often necessitates frequent changing of the dressings, which the speaker thought might possibly be obviated by inserting, in connection with the sterilized gauze, a very small tube through which a small quantity of salt solution could be instilled continually for the purpose of washing out the wound.

Dr McBurney said he did not think the suggestion made by Dr Smith would meet the indications. Take, for example, a large suppurating wound in the thigh, which is filled with gauze with the idea that the gauze should absorb all the infected discharge instead of allowing it to lie in contact with the wound. The theory of this is correct, but the method in which it is usually carried out is open to criticism. In most hospitals such a wound is dressed every other day, in some every three days, no matter what the condition of the gauze may be. Now what happens to the gauze may be this: Perhaps after six hours its capacity for taking up fluid has been exhausted, and if the interval between the dressings is forty-eight hours, the gauze, saturated with septic material, will be left in contact with the wound for forty-two hours, whereas if the gauze is changed at frequent intervals the removal of septic products from the wound will be continuous.

Dr Bryant said he thought it was time to raise an emphatic protest against the so-called "packing" of wounds. He recently saw an infected wound which was so tightly packed with iodoform gauze that the underlying pus could not escape. Only sufficient gauze should be put in to properly drain the wound.

Appendicitis or Colitis.—Dr BEVERLEY ROBINSON, M.D., said that the differential diagnosis between appendicitis and mucous colitis may be at times very difficult. I have seen at least one case in which it was impossible, I believe, at first to differentiate the two diseases accurately. Indeed, I am inclined to believe now that the diseases were combined, and that the attack originated in the colon, then extended to the appendix and finally fixed itself again more especially in the colon.

In colitis the pain may become localized over the appendicular region, the resistance of the abdominal wall may be more pronounced over this region; with nausea or vomiting, high temperature, quickened pulse and respiration, we have pretty much the same symptoms as in appendicitis. In colitis the bowels may be loose in the beginning, but without showing mucus, blood or any undigested food. Later and with freer and more abundant evacuations, a considerable amount of bile-colored mucus is apt to show itself in the stools, and then with, perhaps, a somewhat lowered temperature, a diminution in the localized pain and a more relaxed, less distended abdomen, we are led to make the diagnosis of concurrent colitis with little or no cause for reasonable doubt. In either case I am inclined to believe that much the same treatment is indicated, short of operative interference. The great difficulty arises when we ask ourselves, should a laxative or purgative dose be employed? If, unfortunately, the appendix be ulcerated, on the point of perforation, or already perforated, a laxative may do great and immediate harm, perhaps directly occasion perforation, peritonitis and collapse. On the other hand, if we give laxative remedies, we may be able rapidly to change and ameliorate most threatening symptoms and avoid the necessity of operation. It is for the careful, wise, and conscientious practitioner to decide, and his mind is sometimes almost equally balanced on one side or the other. If careful consideration of the debut and course of the case points somewhat toward colitis, I advise the use of small doses of calomel and soda at half-hour intervals, followed later by castor oil. In one case this treatment settled the diagnosis and the recovery beyond peradventure, and by medicinal agents alone.

Dr McBURNEY said he had seen quite a number of cases of chronic colitis where the question was raised as to whether the condition was not really a chronic appendicitis, but he had never seen a case of acute appendicitis of so grave a nature as to make it unsafe to give a laxative or injection for fear of producing perforation where the question was raised as to whether the condition was really an acute appendicitis or acute colitis. When perforation is threatened in acute appendicitis, the diagnosis is usually not difficult to make.

Dr McBurney said he had also seen one or two cases of unmistakable chronic colitis which were entirely cured by removal of a diseased appendix. This would seem to indicate that the inflammation in these cases had begun in the appendix and extended to the colon; the primary and chief lesion, however, being in the appendix.

The Etiology of Pernicious Anæmia.—Dr CHARLES L. DANA said that about a year ago he read before the Society a paper on the etiology of pernicious anæmia, in which he advanced the hypothesis that the disease was a teratological disorder, due to a primary defect in the hæmatogenous organs, producing premature old age of the blood. In support of this theory he reported at the time a fatal case of pernicious anæmia, the patient being one of a family of fourteen, all of whom, but one, had died in early life.

Since presenting that paper, Dr. Dana said, he had investigated this subject more fully, and he found that, as a rule, the family history of these patients had not been carefully studied. Recently, the following case came under his observation: The patient was a woman, fifty-five years old, who had apparently suffered from pernicious anæmia only about two years, but previous to that time she had suffered from nervous symptoms, such as ataxia, paræsthesia and paraplegia. The nervous symptoms began about four years ago, so that apparently they antedate the pernicious anæmia. Upon inquiry it was learned that the patient's grand-parents were apparently healthy; her mother was eighty-nine years old and enjoying good health; her father had died of cancer at the age of sixty-nine. Her mother had seven children and one miscarriage, making eight pregnancies altogether. Of these children, three sisters died of phthisis rather early in life. There was no phthisis in the antecedent family history. One brother died, apparently, of rheumatism and Bright's disease, but his daughter states that his symptoms during his last illness were similar to those of his sister, who is now suffering from pernicious anæmia. Another brother died of what was said to be an accident. One sister is living, and one sister who died had a child who has epilepsy. Three of the other grandchildren are said to be peculiarly high-strung and nervous.

Dr. Dana's patient was a woman of good physique and mental qualities up to the time of the onset of her illness. Her family history, however, plainly shows the influence of a progressive degeneration, and it would be interesting in all cases of pernicious anæmia to carefully investigate the family history in order to ascertain whether it has any bearing upon the etiology of the disease.

Salivary Calculus.—Dr BRYANT showed a salivary stone which he had removed from the sub-maxillary duct. It weighed twenty grains and was an inch and one-quarter in length, which is about the usual length of the duct in which it was moulded. The calculus had bothered the patient for about six months. It had given rise to considerable pain, due to obstruction of the duct.

New Instruments.

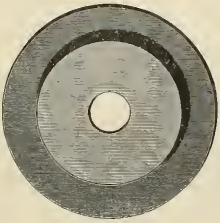
DRAINAGE TUBE FOR PLEURAL CAVITY.

By FREDERIC N. WILSON, M.D.,
NEW YORK CITY.

THE drainage tube pictured and described below was devised for the drainage of the pleural cavity in cases of empyema, and is herewith presented to the profession after a year's uniformly satisfactory use, covering a considerable number of cases.

The objects in view when I devised this tube were:

First—To provide for free and sufficient drainage.



Second—To guard against the tube falling into the pleural cavity.

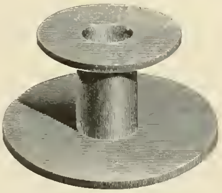
Third—To guard against the tube falling out and thereby interfering with the drainage.

Fourth—To permit free expansion of the lungs to the chest wall without doing any damage to the pulmonary pleura.

Fifth—To provide a drainage tube which should be self-retaining and at the same time easy both of insertion and removal.

This tube is of rubber, in the shape of a spool, and has been made for me, in two sizes, by Mr. P. C. Lorenz, New York City.

The dimensions of small size for children are: Tube length, $\frac{5}{8}$-inch; thickness, $\frac{1}{8}$-inch; diameter of lumen,



$\frac{5}{16}$-inch. Small cuff, which goes inside pleural cavity, diameter, 1$\frac{1}{4}$ inches. Large cuff, which is applied to the skin, diameter, 2 inches.

Dimensions of large size for adults are: Tube length, 1$\frac{1}{2}$ inches; thickness, $\frac{1}{8}$-inch; diameter of lumen, $\frac{5}{16}$-inch. Small cuff, 1$\frac{1}{2}$ inches. Large cuff, 2 inches.

The small cuff is thin and soft, so it is easily folded upon itself and passed through the opening in the chest wall and into the pleural cavity without difficulty.

The cuts show the tube viewed from end and side respectively.

106 WEST FORTY-SEVENTH STREET.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 5, 1902.

	Cases	Deaths
Measles	639	20
Diphtheria and croup	301	35
Scarlet fever	335	29
Smallpox	66	12
Varicella	83	
Tuberculosis	316	165
Typhoid fever	27	10
Cerebro-spinal meningitis	..	4

Climate of Panama and Nicaragua.—General Henry L. Abbot has recently discussed the climatic conditions that obtain along the lines of the proposed Panama and Nicaragua canals. Throughout the entire year the temperature varies but little from the annual mean of 79 degrees Fahr. High temperature and high relative humidity forbid hard manual labor on the part of white men. The hospital records of the Panama Railroad Company for the past twenty years show that there is no reason to apprehend serious trouble from sickness in the future. At Colon the annual rainfall is about 120 inches, in the interior it is about 94 inches, and on the Pacific Coast the precipitation is about 57 inches. There is a dry season of about four months everywhere along the route of the Panama Canal, and the difficult engineering operations can then be carried on. General Abbot concluded that the conditions are less favorable on the Nicaragua route. Near the Gulf Coast, where the heaviest excavations are required, the rainfall is about 250 inches and there is no dry season. On the Pacific Coast and in the interior there is a dry season, though the rainfall is everywhere greater than along the Panama route.

Instruction in the Care of the Teeth.—Instruction in the care of the teeth ought to be made part of the elementary school course in physiology and hygiene. So much depends upon cleanliness and health of the mouth and the teeth that the reasonableness of this proposition will be at once recognized. The decay of the temporary teeth may work lasting injury. Digestion is frequently impaired by imperfect mastication, due to defective molars. The presence of microbes bred in particles of food left between the teeth is often the source of serious stomach troubles. Nervous difficulties of various kinds can be traced to neglect of the teeth, and the inference that the development of serious lung diseases has resulted from a neglected mouth, is by no means far-fetched. The wisdom of increased attention to the education of children in the things affecting their present and future health and strength is evident to every intelligent adult. Therefore no opposition from school officers ought to be encountered in introducing lessons on the care of the teeth and mouth in the elementary schools."—*School Journal.*

Kipling and the Military Hospital Authorities in Cape Town.—The last time Mr. Kipling was in Cape Town he discovered in the neighborhood a military hospital which was without bandages, and very badly in need of them. The shops in the town had lots of bandages for sale.

He mentioned the matter to a friend and said that he would supply the want. Whereupon his friend rejoined that he would pay for all the bandages that Mr. Kipling would take to the hospital.

A wagon was loaded, and then Mr. Kipling learned that, according to regulations, a hospital was not allowed to receive supplies from private individuals.

"Well," said the author, "I will dump the packages on the pavement before the hospital door, then go in and tell them to come out and clear up the rubbish. Perhaps in that way they can manage to smuggle them into the building without having any red tape."

He then drove off with the bandages, and somehow or other the goods were smuggled into the hospital.

Swedish Census.—The Swedish census, according to an English journal, shows the lowest death rate ever recorded by a civilized nation. During the last decade it had been 16.49 per 1,000. Norway comes next with 17.9, then England with [illegible]. Thus the Scandinavians are now the healthiest race in the world. At [illegible], in Lincolnshire, only twenty-five deaths occurred last year in a population of 2,5[illegible].

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended April 12, 1902:

ABDOMINAL ECHINOCOCCUS CYSTS.*

BY FRANK HARTLEY, M.D.,
ATTENDING SURGEON, N. Y. HOSPITAL.

THE infrequency with which echinococcus cysts of the addomen are reported is not surprising when we consider that a cyst not affected by disease or injury, not large or accessible to palpation, easily escapes the observation of both patient and physician, unless its location disturb the function of a neighboring organ, or of the organ in which it is situated.

Of the four cases I report three have involved the liver, and one was situated in the recto-vesical culdesac. Of the abdominal organs the liver is the seat of these cysts in 47 per cent. of the cases, with the right and left lobes occupied in the ratio of 14 to 1. Nearly 70 per cent. of these cysts occupy the lower surface of the organ, and grow toward the peritoneal cavity, where but little resistance is offered by the neighboring soft and mobile organs.

The majority of cysts occupying the anterior segment of this surface are accessible to both palpation and percussion, while those situated in the posterior segment are not accessible to palpation until quite large. In some instances these cysts have rotated the liver upon a transverse axis, displacing it forward, and depressing its anterior border to such an extent as to completely mask the cyst, and to suggest a simple enlarged organ.

In other instances (Most[1]), cysts which have not been accessible to palpation, and have not displaced nor distorted the shape of the liver, have nevertheless caused symptoms by their pressure. Most[2] mentions two such cases, in which he was unable, until operation, to distinguish between an echinococcus cyst and cholelithiasis, in one case, and, in another case, between chronic suppurative cholecystitis and an echinococcus cyst. Körte[3] also mentions two cases strongly and wrongly suggesting cholelithiasis and suppurative cholecystitis, and cholelithiasis and cholecystitis.

Some cases reported by Neisser,[4] Davaine,[5] Arndt,[6] Weber,[7] and Körte,[8] in which a communication had taken place between the bile ducts and the cyst, and in which vesicles, or shreds of membrane, had passed through the ducts, gave a very true picture of cholelithiasis, with and without jaundice. Again, Liholzky,[9] Bahr,[10] and Lehmann[11] mention four cases where, owing to the pressure of an echinococcus cyst upon the pylorus, stomach, and œsophagus, gastralgia, vomiting, and nausea after eating had persisted for very long periods of time. Most[12] reported such a case, where the pressure involved both the œsophagus and pylorus. McArdle[12] operated successfully upon an echinococcus cyst situated beneath the liver, and adherent to the gall bladder, colon, and omentum. This cyst compressed the cystic duct, causing hydrops of the gall bladder and the colon, causing symptoms of ileus. Cysts occupying this surface have had communication with the intestinal tract, and without the slightest symptoms pointing to such an event. Such a case was operated upon, and reported by Krause.[14] Rarer cases where communications have taken place between the intestinal tract and the cyst, and have been followed by infection of the cyst, are reported by Madelung[15], and by Barbillon.[16] In the former case the colon and the cyst communicated. In the latter the stomach and the cyst. In both cases the contents of the viscera revealed the echinococcus membrane. A cyst situated in the region of the liver, and producing scarcely any pressure symptoms, is the following:

R. B., aged twenty-five years, Italy, New York Hospital, November 27, 1897. Personal history: He is, and has been, an exceptionally healthy man. Family history is negative. For the first time, eighteen months ago, he noticed a dull pain or ache in the right hypochrondium. This pain has been gradually increasing in severity. One year ago he noticed that the side was becoming steadily larger, but, beyond this symptom, he has not suffered from anything save an attack of jaundice, six months ago, which lasted a period of three weeks. Since the attack of jaundice, he has been in good health. His only complaint has been the dull pain, and the increase in size of the right hypochondrium. He has lost no flesh or strength. On admission to the hospital his temperature was 99°, respiration 24, pulse 100. The urine was clear, acid 1020, no albumen, no sugar; microscopically, uric acid crystals. The physical examination showed the heart and lungs normal. The liver dulness was increased. It extended about three inches below the costal arch. The margin of the liver could be felt. It was sharp, well defined, and normally regular. On deep palpation, below and behind the margin, and apparently not connected with the liver, was a smooth, elastic mass. This mass appeared not larger than a good-sized orange. It moved with the liver during forced respiration. It was situated in the parasternal line. The abdominal examination otherwise was negative. The diagnosis made was that of an echinococcus cyst, situated within the right lobe, and projecting below the inferior surface. The jaundice was thought to have occurred independently of the cyst. Operation, December 2; ether.

Longitudinal incision, five inches through the right rectus muscle. The abdominal cavity was opened. The liver, which was rotated upon a transverse axis, and was displaced downward, had to be lifted in order to expose its inferior surface, and reveal the tumor. The tumor was found situated in the posterior half of this surface, and was covered by a layer of liver tissue about 1 cm. in thickness. The tumor was firmly fixed, and so immovable that it could not be made to approach the abdominal wall by several centimeters. The projecting mass of this tumor lay in front of the kidney, and to the outer side of the duodenum (one and two parts), and beneath the gall bladder, en-remaining upon each other, yet not producing symptoms in any. A careful examination of the liver revealed no other cysts, nor could any cysts be felt elsewhere in the abdomen. It was thought advisable to pack the wound, then the abdominal wall to the level of the tumor, after closing the greater portion of the wound. Just before applying the final dressing about one-half of the fluid in the cyst was removed by aspiration, and a solution of corrosive sublimate (1:1000) was injected into the cavity, where after a few minutes it was for the most part removed.

---

*Read at the June meeting of the Society of the Alumni of Bellevue Hospital.

December 7.—The dressing was removed, and a second aspiration was made of the cyst, liberating about 10 oz. of a clear fluid. The inner wall of the cyst was torn from vesicles. The chitin, or cuticular membrane, was removed as thoroughly as possible. As the cyst was immovably fixed, and would not contract, it was deemed advisable to pack it with gauze. The recovery from the anesthetic was satisfactory. The wound was dressed every three days.

December 29.—A small portion of the cuticular membrane came away to-day.

January 2.—Patient is about the ward, with a small sinus, from which he has no discomfort. The fluid removed was sterile. Hooklets were found.

January 10.—Discharged.

January 31.—Patient returned to-day with his sinus completely healed. Upon the superior surface of the liver these cysts are less frequently found, and, as they are often situated upon the posterior half of this surface away from observation, they are less accessible to palpation. As they increase in size those upon the anterior half antevert the liver, depressing its border below the thoracic costal arch, and appearing as an elastic and sometimes fluctuating mass below the thorax, above the liver, and closely applied to abdominal wall. Nine such cases have been reported: Löbker one[17], Neisser five[18], Fick, one[19], Krasnoff and Kolpatschki, one[20], and Most, one.[21] The remaining cysts upon the surface usually occupy the posterior half, and are so well concealed that, when recognized, they have already acquired an unusual size. The latter usually retrovert, or tilt the liver to one or other side, and, at the same time, produce an atrophy and upward displacement of the diaphragm resulting in compression of the lung and widening of the inferior thoracic aperture. All echinococcus cysts occupying this surface are not necessarily primary occupants of the liver tissue. The retroperitoneal tissue behind the coronary ligaments is directly continuous with that behind the intestine, the kidney, the pancreas, and the spleen, and the latter three organs are in contact with the diaphragm, so that infrequently subphrenic cysts may originate in these tissues and organs. Of these we mention the spleen, the kidney, and the retroperitoneal connective tissue. As the spleen harbors only 3.16 per cent. (Trinkler) to 3.5 per cent. (Frey) of all echinococcus cysts presenting within the abdomen, its frequency as a seat for subphrenic cysts is correspondingly small. Trojanow[22] who reports twenty-one cases collected in the Russian literature, does not mention a single case.

M. Wolff,[23] Maydl,[24] Madelaine,[25] Donat,[26] Quenu,[27] Guibe,[28] Reboul,[29] Alessandri,[30] Holstein,[31] and Aschoff,[32] have each reported a case originating within the spleen, and in its growth becoming subphrenic rather than advancing in other directions. Of these cases two were suppurating at the time of operation, four were complicated with pleuritis, one with bronchopneumonia, three with perforation of the diaphragm and suppurative pleuritis.

According to Frey, echinococcus cysts of the kidney represent 12 per cent. of all cases involving the abdominal viscera. These so-called renal echinococcus cysts, many of which originate in the perirenal connective tissue, usually empty into the pelvis of the kidney, and less frequently in the intestine, lungs, or through the lumbar fascia externally.[33]

Simon mentions six cases arising within the kidney, one in the capsule, and two whose origin in the kidney was doubtful. L. Mananne[34] cites fifty-one cases originating within the kidney, with only one case as a subphrenic cyst.

Jarosch,[35] who collected eleven cases, and saw two cases, does not mention one as a subphrenic process. The noteworthy case of Roux quoted by Maydl,[24] remains, therefore, quite as isolated as it did in 1894.

Cysts originating in the retroperitoneal connective tissue as primarily subphrenic, or becoming, by growth and extension, secondarily subphrenic, are rare. In Maydl's seventeen cases of subphrenic cysts, three only might have had such origin. In almost all instances cysts occupying this locality have been extensions from the subpleural space, the pleura, lungs, the spleen, kidney, and liver.[24] A case occupying the posterior half of this surface of the liver, and presenting a typical subphrenic abscess, is the following:

John D., thirty-two years old, Austria, laborer. August 2, 1896, Roosevelt Hospital. Family history is negative. Personal history, syphilis two years ago. Two years ago he was struck by a stone upon the right chest wall, and since that time he has felt pain at the spot.

On July 10 he was admitted to the medical wards, with the history of fever, pain in the right chest and epigastrium, loss of appetite and sleeplessness, extending over a period of several weeks.

Examination.—Nutrition is fair. There was slight jaundice, slight cough, and tongue is coated. There was pain upon pressure over the right chest, from the sixth rib down to the costal border. It was not marked in the epigastrium, where there was little or no tenderness. Flatness to percussion was present from the sixth rib to two inches below the costal margin of the right side. This flatness was not altered in position. The shape of the thorax was altered in that it was wider than usual at the costal margin. These manifestations together with the physical signs of compression of the lung above the sixth rib (the failure of breathing and voice fremitus), the area of flatness below the seventh rib, the apparent increase in liver dulness, and the evident displacement downward of the liver, led to the diagnosis of a subphrenic collection of fluid. By deep inspiration the vesicular breathing was heard below its former level, so that the lung and the cystic cavity were probably separate. Moreover it was probable, owing to the absence of cough, expectoration, dislocation of the heart, and the natural intercostal spaces, that this cavity was not an empyema of the thoracic cavity, although it might have been a sacculated one.

The temperature 100°-102°; pulse, 72-92; respiration, 20-24. A needle inserted in the eighth space obtained a clear fluid, which, upon examination, revealed the presence of hooklets.

The diagnosis was then assured, and the location of the cyst was thought to be subphrenic.

August 3.—Operation. Ether narcosis.

A curved incision, four to five inches in length, over the seventh, eighth, and ninth ribs, between anterior and posterior axillary lines, was made, exposing these ribs. A resection of four inches of each of these ribs exposed the subpleural connective tissue. An exploring needle was inserted into the pleural cavity, and, no pus being found, the diaphragmatic and costal pleuræ were incised and sutured, so as to close off the pleural cavity. This was necessitated because of the adhesion of these layers, and the obliteration of a small portion of the pleural cavity. After reënforcing the line of suture between the diaphragmatic and costal pleuræ with sterile gauze packing, the needle was inserted through the diaphragm into the abscess. The abscess cavity, being apparently adherent to the diaphragm, an incision two and one-half inches long was made through it, and into the cavity. It was necessary, in entering the abscess, to pass through about one inch of liver tissue. Through the incision, numerous cysts, varying in size from a marble to an egg, and containing clear or slightly turbid fluid, escaped. The fluid escaping with the cysts was sero-purulent, and mixed with blood and bile. The cavity was thoroughly washed with hot salt solution, and many pieces of the cuticular membrane were removed with the forceps. After the cavity, which occupied the greater portion of the right lobe, and seemed to be bounded by the liver upon its lower and outer aspects only, was thoroughly cleaned, it was packed with sterile gauze, to give support to the tissues surrounding it. A sterile dressing was then applied to the transpleural wound.

August 4.—The outer dressing was soaked with a bile-tinged sero-sanguinolent fluid. The condition of the patient was good. The dressing was changed.

August 5.—Dressing was changed twice. The discharge seems less tinged with bile. The inner packing removed. The cavity seems small already. Temperature, 99°; pulse, 100.

August 7, 8, 9, 11 and 13.—Dressing changed daily. The cavity is gradually becoming smaller. The bile still stains the gauze.

This same treatment was continued until September 30, when the wound was healed and the patient discharged as cured.

Another case occupying this surface of the liver, but in the anterior segment only, is the following:

O. G., twenty-eight years old, October 18, 1900, Germany. Was referred to the New York Hospital on account of a swelling in the epigastrium, which was first noticed after recovery from a grippal bronchitis. Neither pain nor discomfort was experienced from this swelling. Unless he had noticed the deformity, he would not have spoken to his physician. The patient was somewhat anæmic. His tongue was clean, his appetite good, and his bowels regular. Urinary examination was negative. There was no jaundice. His pulse and temperature were normal. In the epigastrium, a little to the left of the median line, a tumor extended as high as the costal arch above and to the umbilicus below. The mass by palpation was, probably, three and one-half inches in its transverse and vertical diameters. It was dull upon percussion, and seemed to move with deep inspiration. The anterior margin of the liver was lost in the lower portion of the mass. As no temperature, pain, or previous history of functional disturbance in the abdominal organs, existed, and as the tumor seemed to be attached to the liver above, the diagnosis seemed to point to echinococcus cyst or sarcoma. Its absolute freedom from pain, its elastic resistance, and its smooth contour pointed to an echinococcus cyst rather than to sarcoma. An exploratory operation was advised and accepted.

October 13.—Ether Narcosis.

A median incision, extending from the xiphoid cartilage to below the umbilicus, was made. The peritoneal cavity was entered, and a cyst was seen occupying the upper surface and anterior border of the liver. Probably two-thirds of the circumference of this cyst was covered by peritoneum alone, so that, in an enucleation, only one-third, involving the liver, required careful work. With a fine syringe, one-half the contents were removed, and were replaced with a solution of bichloride (1-500). After five minutes the contents were removed as much as possible, only a very small amount of fluid remaining in the sack. The cyst was now circumvented with an incision, leaving a cuff of peritoneum and subperitoneal tissue. The cuticular membrane was removed intact. The hemorrhage was moderate in amount, and though the arteries were not easily caught and ligated, they responded readily to cauterization and pressure. Two large catgut ligatures were passed through the liver beyond the margins of the depression. They were lightly tied, and just opposed to the wounded surfaces. As this seemed sufficient to stop the hemorrhage, the abdominal wound was closed after a negative inspection of the liver, spleen, kidney, and omentum.

October 14.—Patient is in good condition; temperature and pulse practically normal.

October 21.—Dressing changed, primary union, stitches removed.

October 30.—Patient discharged cured.

November 29.—Patient was examined to-day. The scar is solid and movable upon the underlying tissues (liver); no apparent tendency to a hernia. In none of these three cysts occupying the liver was the hemorrhage a factor in the after-treatment, nor was there any significant flow of bile. This is the usual case, even where incision and drainage of the cyst have been used. In a few instances, however, a greater portion or all of the bile has been passed in this way, and its loss has been very differently tolerated by different individuals. While Wechselmann[37] and Krause[38] have seen a rapid convalescence after a few weeks of such escape, and Israel, after ten months, has seen a gain of five to six pounds in weight, Genzmer,[39] König,[40] Fick,[41] Most,[42] and Körte[43] seem to believe that patients so suffering are greatly weakened, and easily succumb to any intercurrent processes. The usual cause of the escape of bile is seen in the rupture of the innumerable varicose biliary vessels upon the circumference of a growing cyst, when its contents are suddenly emptied. This rupture is followed by the escape of bile, until granulation, cicatrization, and contraction of the newly-formed tissue closes its vessels. When, however, the stools are acholic, and persistently so, together with the escape of a large quantity of bile from the wound, either the common or hepatic ducts are obstructed. This obstruction has been found to be due to (1) A second tumor[44]; (2) To vesicles or portions of the membrane which have been forced into the ducts[45-48]; (3) To the development within the ducts of the echinococcus vesicles,[49-54] or, (4) An independent catarrhal inflammation of the ducts.

In not one of our cases have we been able to find more than one cyst, although as many as twenty have been seen in the liver. In such typical cases as 1 and 3, where the cysts were situated upon the anterior segment of the upper and lower halves of the liver, the diagnosis was reasonably safe, owing to the smooth, elastic mass presenting. No ex-puncture needle was used lest the contents of the cyst might escape along the needle tract, especially if the cyst wall was thin and not covered by liver tissue, and give occasion to multiple implantation cysts,[58] to an aseptic peritonitis,[59] to a foreign body tuberculosis of the peritoneum,[60] or to a septic peritonitis. The latter result may occur where the fluid withdrawn by the needle is clear and aseptic, for the needle may have punctured a daughter cyst the contents of which were clear, while the fluid escaping along the needle puncture wound from the mother cyst is purulent and septic (Körte).[6]

The conditions presented by cysts occupying the superior surface and posterior border are very different from those presented by cysts upon the anterior half of the upper and lower surfaces of the liver. Here the needle is used in spite of its danger,[62] as it is the only means we have of telling whether the immediate line of flatness is liver or fluid, as well as the nature of the fluid and the necessity for a transperitoneal incision.[63]

The next case I present is one involving the pelvic peritoneum between the bladder and the rectum.

J. B., admitted to New York Hospital, February 9, 1898, aged 34 years, Italy. Discharged April 24. Family history is negative. Previous personal history, gonorrhœa ten years ago. Three months ago patient began to have pain over the lower half of the abdomen. Two months ago patient noticed a tumor on the right side of the abdomen, which increased in size for a month and a half, and has remained stationary for the past two weeks. The pain subsequently shifted to the right side, where it has remained until the present time. The pain was dull in character, and was constant. It has not increased in severity. It was independent of the ingestion of food, or of a movement of the bowel. The patient has been constipated. His bowels have moved only with medicine. He has passed no blood per rectum. His urination has been painful and frequent, but he has never passed pus nor blood.

Examination on Admission.—Temperature, 98.8°; respiration, 28; pulse, 88. The abdomen is so tense that nothing can be discovered by palpation. The lower half of the abdomen is protuberant, is flat upon percussion, with a resonant border upon each side of the flatness. There is a slight suspicion of a fluid wave transmission. In all other respects the patient is a perfectly healthy man.

Diagnosis.—Probable echinococcus cyst.

Operation October 16. Ether. A median incision carried through peritoneum revealed the wall of a cyst close to the abdominal wall. Examination by the hand showed a cyst occupying a large part of the abdominal cavity. Upon the posterior surface of the cyst the wall was very thin, and during the manipulation of the abdominal pads, before opening the cyst to empty it, it ruptured, allowing an escape of fluid and cysts into the abdominal cavity. The patient was then turned to the side, and the opening enlarged sufficiently to allow a complete emptying of the cyst. After this unfortunate turn of affairs it seemed only possible to clean the abdomen by a complete evisceration, and a minute inspection of every organ and cavity in the peritoneum, for the cyst held one and one-half buckets full of fluid and smaller cysts. In order to be certain, it was necessary to go over the field twice, and each time to wash the intestines and the surface of the organs with large quantities of hot sterile salt solution. This was accomplished, and every portion of this cavity was seen, including the lesser cavity of the peritoneum, so that, so far as inspection was possible, every cyst was seen and removed by hand. The echinococcus cyst was now examined, and was separated from its intestinal adhesions. All that portion of the cyst wall which was free was removed, and only that portion closely adherent to the peritoneum of the rectovesical space was left. From this portion the cuticular membrane was removed with the greater portion of the connective tissue capsule. That portion of the connective tissue capsule remaining adherent to the rectovesical peritoneum was inverted upon itself and sutured. Owing to the extensive manipulation necessary to free the cyst, and the tearing of adhesions, it was deemed advisable to pack the cavity with gauze. The abdominal wound was sutured with catgut and silk, except at a point for the exit of the gauze packing. A sterile dressing was applied.

February 17.—Wound healed, except for drain.

March 2.—Wound almost healed.

March 19.—Wound healed except for small sinus.

April 24.—Patient discharged cured.

Heincke[65] says that but few solitary echinococcus cysts of the peritoneum are known, and even of this fact there is an uncertainty, because none came to autopsy. Scheerenberg's case, which was thought to be a solitary cyst of the omentum, proved, after death, to have had two small cysts in the liver, besides the omental cyst.

Most[66] says that a single echinococcus cyst of the peritoneum has not yet been observed. The parallelism is exactly what has been seen in the omentum where, of all the cases in which a solitary cyst was clinically diagnosed, only one came to autopsy, and in that case two cysts were found.

Gummiel's[67] case, in which an echinococcus cyst was removed from the omentum, also had smaller cysts situated upon the fundus uteri.

Chroback's case,[68] in which a subserous echinococcus cyst filled the whole pelvis, and protruded into the vagina, was accompanied by a second cyst originating from the liver.

So it is with some reserve that I report this case as a single one of the pelvic peritoneum, and had not the very accident happened which did, and had I not been forced to carefully go over every organ and part of the peritoneal cavity, I would not now report it as such. I only now say that, in so far as our examination went, no other cyst could be seen or felt in the peritoneal cavity. It is not surprising that solitary cysts of the peritoneum or omentum are so rare, for the method of emigration from the intestine is actively participated in by the embryo, which, entering either lymph or arterial vessels, the peritoneal cavity, or the subperitoneal tissue, is thus easily distributed in these localities.[69]

Again, multiple peritoneal cysts are not infrequently the result of rupture of primary liver cysts.

In my particular case the embryo may have easily traversed the retroperitoneal connective tissue and, locating in the pelvis, having developed toward the cavity, subsequently presented itself as an intraperitoneal cyst. As will be seen in the treatment of these cases, no single method has been pursued, and for the reason that cysts occupying the various organs or tissues necessarily present such varying conditions as to demand different methods of operation.

The older methods of puncture and injection into the cyst cavity of solution of corrosive sublimate (Bacilli and Lennet), of an iodoform oil emulsion (Billroth), of the tincture of iodine (König), have been generally abandoned, because of the danger of leakage through the puncture opening, or from the general intoxication which has resulted from the drugs employed. These two dangers, the leakage and the intoxication, are considered avoidable by some. Dieulafoy[71], who treats these cysts by aspiration alone, claims that the danger of leakage is not present when the fluid is removed as completely as possible, and quiet and freedom from pressure upon the cyst is avoided. He operated upon eight cases without accident. Franke, who strongly advocates the use of a 5 per cent. formaline glycerin mixture, especially where the cysts cannot be reached by operative measures, sees no hindrance to healing in the tissue necrosis induced by the formaline.

Again, the older method of incision and drainage has been abandoned on account of the difficulty of keeping the wound aseptic, and of the tendency to the development of hernia and cicatricial bands left between the abdominal wall and the adjacent organs. To shorten the time required to obtain a cure by this method (Körte, two and one-half months; Carré, three to six months), Richelot, Reclus Monod, Terrier, and others have resected large portions of the cyst wall, and, after having sutured the margins to the abdominal wall, have drained the cavity as in the operation of simple incision. The reduction in the time was marked. In Körte's cases the average time required was one month and twenty days.

To avoid the marked intoxication following the use of iodoform, Bobrow* made use of an indifferent fluid. He cleansed the cyst of its contents. He replaced its contents with the normal salt solution, and sutured the incision in the sack. He expected the presence of bile, blood, or serum in the cyst would be avoided, owing to the gradual absorption of the salt solution. He soon found it unnecessary to use the salt solution. It was quite sufficient to cleanse the sack thoroughly, and to close it by suture.

At about this time Delbet introduced the method of "Capitonnage."[72] This method consisted in emptying the contents of the sack, in removing its chitin membrane, and in incising as much as possible of the sack wall. After this was accomplished, the cavity was closed by invaginating its walls and suturing the apposed surfaces. This was the method employed in our pelvic cyst.

These two methods have undoubtedly succeeded in shortening the time of cure, and have diminished the danger of suppuration in the cyst or the neighboring cysts. They have also avoided the frequent and long-continued loss of bile in the cysts of the liver. Yet their relative value has been questioned by many surgeons. Delbet[73] considers capitonnage the normal method, and only in suppurating cysts and those with calcified walls does he consider the method inapplicable. Bullinger[74] and Körte[75] disapprove of these two latter methods, because of the danger of overlooking vital daughter cysts, and of the possible stagnation of slightly infected bile within the cyst cavity, and a subsequent acute infectious cholangitis. The same objections may be made against Jonnesco's[76] method of evacuation, removal of the mother cyst, dry cleansing, and suture of the cyst wall. Quenu[77] considers it a drawback to the operation of Delbet that the want of elasticity often prevents a complete closure of the cyst cavity. Tuffier[78] acknowledges the probability of leaving behind daughter cysts capable of further development, and advocates a curettage of the cyst wall, and washing with a solution of common sublimate. Jonnesco,[79] who strongly inveighs against all washings, whether aseptic, antiseptic, or irritant, as useless and dangerous, reserves capitonnage for large non-suppurating cysts in which the elasticity of the wall allows an approximation of the surfaces.

Another method destined to diminish the time, and to avoid the secondary infection, is the enucleation of the cyst.

Pozzi,[80] Palleroni,[81] Beckhaus,[82] Depage,[83] Carré,[84] and Posadas[85] have enucleated these cysts with subsequent tamponade or immediate suture of the cavity, left without drainage or fixation to the abdominal wall. Posadas, who has completed a series of thirty-seven non-suppurating cases, has had twenty-nine cases heal by primary union, three with suppuration, and five die. Posadas enucleates the mother cyst without puncture where small and not closely embedded in the parenchyma of an organ. In large cysts he proceeds in the same way, after puncture and removal of the contents. When cysts are situated entirely within organs which can be sacrificed, it is a question whether it is not wise to remove the organ and cyst together, rather than run the risk of hemorrhage and shock. Both Hahn[86] and Donat[87] have operated in this manner with a mortality of 25 per cent., as against 49 per cent. in the same organ in puncture and drainage (spleen).

With cysts presenting upon the anterior half of the upper or lower surfaces of the liver, or upon the lower segment of the spleen and kidney, it is customary to suture the sack to the parietal peritoneum, and to open the cyst after a complete union. Where the cyst wall is very thin—in fact, so thin that it will not hold its sutures—the cyst is firmly pressed against the abdominal wall, incised and emptied of its contents (Lindemann), after which one proceeds to adopt the method most suitable to the conditions. Undoubtedly the operation of choice is enucleation of the mother cyst, dry cleansing of the fibrous capsule, and a complete obliteration of this cavity by suture.

Those cysts presenting upon the surface of the liver, and, to a great extent, covered by peritoneum only, are most suitable for enucleation. In these, even, if the cyst be large, the amount of liver parenchyma denuded is relatively small and accessible to treatment by tamponade or suture. For these reasons, small, non-suppurating cysts situated in the liver, if accessible, should be enucleated. For those non-suppurating cysts, too intimately associated with the liver to warrant enucleation, and with walls sufficiently elastic to allow a closure of the cavity, the method of Delbet (capitonnage) is preferable to that of Bobrow or Jonnesco. Where suppuration is present, the method of partial resection of the cyst wall, as practised by Terrier and Körte, or possibly the method of Rasumowsky,[88] meet the indications with the greatest assurance of success. In the spleen, the kidney, and the liver, the enucleation of the cysts will always be attended with some risk of hemorrhage. In the liver we also meet the additional risk of the entrance of air into the veins. This has happened to both Israel and to Van Hochenegg,[89] with fatal results in a few hours. That these dangers are to be overcome can be seen by the manner in which hemorrhage has been controlled by hot air,[90] and by hard pressure before ligation (Krause).

For cases situated in the subphrenic space, originating in the spleen, the liver, or in the subphrenic connective tissue, the method recommended by Volkmann and Israel is the most applicable. When the cyst presents either beneath the twelfth rib posteriorly, or beneath the thoracic arch and xiphoid cartilage anteriorly, one may incise directly upon the most prominent area of the cyst. Where the cyst [illegible] [illegible], the trans or per pleural method has to be adopted. As in an ordinary thoracotomy, with resection of portions of one or two ribs, one proceeds until the parietal thoracic pleura is reached. The pleura is usually found to be thickened and adherent to the diaphragmatic pleura, or free, and covering a serous or purulent exudate within the thoracic cavity. The pleural cavity may be intact and contain either a movable or partially adherent lung. In the first instance, a simple incision into the cyst is alone necessary to empty it of its contents; in the second instance, where pus is present as a circumscribed or as a diffuse collection in the thoracic cavity, this is first removed, and when the cavity is clean then the diaphragm is incised for the subphrenic collection.

---

* Bobrow was not the first to do this, though he was the first to carry it out methodically

Where the lung is movable and the thoracic cavity is intact, the diaphragmatic and costal pleura, with as much of subserous fibrous tissue as is possible, are sutured, so as to close off the pleural cavity before incising the diaphragm. This is necessary to avoid a withdrawal of the diaphragm during inspiration, and the escape of fluid into the pleural cavity. If the lung is adherent, and occupies the line of intended incision, it must be displaced, and fixation of the diaphragm and the thoracic wall take place before entering the cyst. In reference to the technique, in dealing with these cases, should be mentioned Budinger's case, where, in order to determine the treatment of a subphrenic cyst, which was mainly intrathoracic, a temporary resection of four costal cartilages was first made, in the form of a flap, with its base above. After a careful inspection, a second resection was made, involving a portion of the sixth rib posteriorly, for drainage. The patient recovered rapidly and without incident.

The Treatment of Itching.—M B Hartzell discusses the various forms of itching due to constitutional or local causes, and their prevention and treatment. No local remedy is so useful as carbolic acid. ℞ Acidi carbolici, ʒss; glycerini, f ℥i; aq. camphoræ, q. s. ad. ℥iv, is a useful lotion to [illegible] rub on the affected parts every four hours. Menthol stands next to carbolic acid, and is best applied as an ointment or paste. Resorcin is good as a lotion in moist forms of eczema. Thymol is often useful, especially in senile pruritus. In pruritus ani and pruritus vulvæ, spirits of nitrous ether painted over the parts with a camel's hair brush every second day will often act most favorably. Painting the vulva with compound tincture of benzoin, or with camphor-chloral has been recommended; when the itching is confined to the mucocutaneous border of the anus a 5 per cent. ointment of cocaine will produce complete temporary relief.—*Therapeutic Gazette*.

TREATMENT OF PNEUMONIA.

STEPHEN SMITH BURT, A.M., Yale; M.D., Columbia.

PROFESSOR OF MEDICINE AND PHYSICAL DIAGNOSIS, NEW YORK POST-GRADUATE MEDICAL SCHOOL; ATTENDING PHYSICIAN, NEW YORK POST-GRADUATE HOSPITAL; AND FORMERLY O. D. DEPARTMENT, DISEASES OF THE HEART AND LUNGS, BELLEVUE HOSPITAL.

Inasmuch as pneumonia is a self-limited disease of short, but variable, duration—that is to say, a specific infection which, from the perishability of its parasite, soon becomes exhausted—neglect of these facts in practice may lead to many therapeutic indiscretions. If the predisposing causes have been slight, and the patient hitherto otherwise sound, there will be a relative slight degree of infection; but if the previous health has been bad, or the antecedent poisoning has been great, or both combined, the gravity of the infection will be in proportion. The natural condition of two persons being the same, the seriousness of the infection will be in direct ratio to the proximate causation; the seed will grow, reproduce, and secrete poison according to the fertility of the medium in which it is planted. However, no two persons are exactly alike in make-up, for each is the particular product of what has gone before in his own life and that of his ancestors. Hence, with a given degree of infection and of poisoning, the patient may or may not be able to survive the ordeal, the alternative largely depending upon his constitution. In other words, the type of the disease, and likewise the results, are chiefly based upon the condition of the individual. A good majority of those attacked in early life, and, indeed, any time before the advent of chronic degenerative changes, recover from pneumonia under various forms of medication, and, what is more, sometimes despite the treatment to which they are subjected. According to my opinion and that of many others, the best method to pursue in the management of this malady is to place the patient under such favorable conditions as quietude of mind and body, abundance of sunlight, good ventilation, simple regimen, and trust the pneumonia qua pneumonia to the inherent capacity of the cellular tissues to work out in due time their own salvation. Considering the future welfare of the patient, the outcome will be as good as, if not better than, any attempt at specific medication. Moreover, experiments with specifics may in the hands of the incautious result in serious harm by overzealousness. Other things being favorable, an early and correct diagnosis will afford the best means for an ultimate convalescence. The recognition of unpropitious symptoms and complications as they arise, and the judicious giving or withholding of remedies will tax to its utmost the perspicacity of the attending physician. While many cases of pneumonia will recover without the use of drugs, a certain number will perish, owing to various causes that are beyond control, in spite of the most skilful nursing and prescribing; but between these extremes there exist numerous examples, wherein the life of the patient will depend upon the ability, judgment, and therapeutic resources of the medical attendant.

Ardent advocates of the specific treatment of pneumonia bring forward in favor of this style of practice enthusiastic arguments and testimonials of varying consequence. This form of medication is maintained to be as reasonable as the same methods of dealing with diphtheria, malaria, syphilis, and acute rheumatism.

The ultimate results of the treatment of acute rheumatism by the salicylates does not seem to me a very good reason for so treating pneumonia. Acute articular rheumatism is, without doubt, a self-limited infectious disease, though of relatively long and of indefinite duration, but the patient is infinitely better off in the end if he has been simply relieved of his pain by suitable external applications, and by opiates and antifebrin if needed internally, than when filled by sodium salicylate, for example, up to the point of saturation.

Syphilis has decreased in virulence in proportion to the reduction of the former overpowering doses of mercury that were administered. In fact, it too, is a self-limited disease, and, granted sufficient time, it will wear itself out as effectually without as with its traditional specific, and leave the patient in a better physical condition than after extended mercurialization. A tonic treatment at most is all that is required in this disease, together with the use possibly of an iodide, not as a specific, but as an intelligent means of favoring cellular activity and the extrusion of morbid accumulations. Although C. H. Fagge[1] concludes, on the whole, that a patient who has syphilis derives immense advantage from a course of mercurial treatment, provided that it is judiciously managed, nevertheless, he makes the following important statement, namely, "It is now an established fact that it is possible for not only the primary lesions of syphilis, but also the various secondary and tertiary eruptions to subside spontaneously without any specific treatment; indeed, this result sooner or later occurs in the large majority of cases when the patient is placed under favorable conditions as regards rest of body and mind, good diet, and pure air."

Nor is quinine, valuable as it is, absolutely essential in malaria, for also this malady is a self-limited infection, and if the patient is removed from its source it will of itself subside eventually. Austin Flint[2] remarks, in writing of malaria, "it is to be borne in mind, in judging of the effects of remedies in this disease, that it tends intrinsically to end after a few paroxysms in a certain proportion of cases," and further, he says in substance, that if there is such a thing as a specific in medicine, it is quinine. and while there is no foundation for the popular notion that its prolonged use in small or moderate doses is prejudicial to health, yet excessive cinchonism is not advisable, for permanent blindness and deafness have resulted from the use of quinine in enormous doses. William Osler[3] says that "after a few paroxysms, or after the disease (intermittent fever) has persisted for ten days or two weeks, the patient may get well without any special medication. I have repeatedly known chills to stop spontaneously," though he adds, "such cases, however, are very liable to recurrence." The much greater value, by the way, of draining the marshes and exterminating the mosquitos than of even so prized a remedy as quinine, should appeal to thoughtful physicians; for instance, in a similar case, while many medical men of a certain turn of mind were puzzling their brains about some specific for yellow fever, such as existed in Havana, another class of investigators were looking, and with success, for its cause and the means of its spread, whereupon further search for this specific became needless· there was no more yellow fever in Havana to be treated. This, however, is another subject, though one that appeals to me as fraught with deep significance. The treatment of diphtheria by antitoxin is likewise cited as a reason for attempting the specific medication of pneumonia. It does not seem to me, however, that there exists a parallelism between these two affections, and though my personal experience does not warrant an opinion upon antitoxin treatment, it would still appear to be debatable, in the estimation of many careful observers, whether or not this remedy is a blessing unalloyed. Some whose views with respect to the treatment of this malady are founded on a large clinical experience, assert that the apparent lessening of the death rate in diphtheria is mainly due to increased refinement of diagnosis, since many instances of the disease that are of a mild type, and were formerly not classified as diphtheria, are now pronounced positively to be diphtheria by means of the regular culture tests of the bacteriologist. Moreover, that antitoxin does not save the lives of those who are most seriously poisoned, and that the milder cases recover under other forms of treatment with less serious after consequences. The fluctuations which occur throughout very long periods, in the type and the prevalence of diphtheria are shown by J. A. Glaser[4] in his exhaustive article upon this topic, and compared to more restricted statistics they are exceedingly instructive. Also DeMaurans[5] shows that "the mortality in 3,842 cases of diphtheria in Paris in 1895, was 9.4 per cent., and in 4,347 cases occurring in 1901, 14.49 per cent. In Berlin, also, the relative mortality, which, in 1895, was 15.7 per cent., and in 1896, 12.3 per cent., rose in 1897 to 13.9 per cent., and in 1898 to 14.2 per cent., in 1899 to 15.9 per cent., and in 1900 to even 17.2 per cent." Furthermore, Gottstein[6] shows that, "according to statistics collected by Bayeux from the total literature on the subject, 207,257 cases of diphtheria treated with antitoxin gave a mortality of 16.2 per cent., while the average of mortality in the period preceding the use of antitoxin in Hamburg, 1872-94, was 15 per cent., in Munich, 1888-94, 12 per cent., and in Basel, 12 per cent. The total statistics of Bayeux prove that even after Behring's treatment, one case out of six dies." Finally, there is no better illustration of the self-limitation of the infectious diseases, and the absence of an absolute necessity for their so-called specific treatment under proper management, than that of the renowned physician, the late Alonzo Clark in regard to typhus fever in the wards of Bellevue Hospital. "At one time," it is related, "he had 250 cases of this infectious and contagious disease under his care, and there were as many more under the care of his colleagues. The mortality was great. Although it was winter, the windows were removed, stoves were placed before the open spaces to warm the incoming air, and except for moderate stimulation, no other medicine was given. Not one of the 250 cases died, and in two weeks they were convalescent." Austin Flint[7] recounts a similar experience, to wit: "In a paper communicated to the New York Academy of Medicine, in June, 1853, by Dr. John H. Griscum, an account is given of eighty-two cases of typhus transferred from an emigrant ship at Perth Amboy, N. J., to wooden shanties. There being no hospital nor other accommodations in the town, two shanties were erected thirty feet long and twenty feet wide, boarded on three sides about four feet up, and over them old sails were stretched. Eighty-two fever patients were transferred to these shanties, of whom twelve were in a state of insensibility when removed. The medical treatment consisted of an occasional laxative or enema, vegetable acids and bitters were liberally administered, together with the free use of cold water, buttermilk, and animal broths. Of the eighty-two cases treated in these shanties not one proved fatal." Instead of looking forward hopefully to a time of more specifics, my prevision is that infectious diseases will eventually be things of the past, and, moreover, from what is now taking place by means of sanitation, there is good reason to predict so desirable a consummation. For example, cholera, typhus fever, bubonic plague, yellow fever, pulmonary tuberculosis, and even typhoid fever and malaria already, either wholly or in part, have been eradicated from many communities. Therefore it is only a question of extension of time and intelligence when these scourges of the human race will be entirely extirpated.

If physicians would but test the effects of much of their medicine upon themselves, and meantime, being entirely frank, would carefully analyze their sensations, it is within the bounds of possibility that they would conclude that the deleterious action upon the system of this medicine frequently outweighs the good that can be therewith accomplished. At all events, it is my opinion that the use of remedies in what is thought to be requisite dosage, such as creosote, creosote carbonate, sodium salicylate, mercury, carbolic acid, and pneumococcic serums are unnecessary, to say the least, in an acute self-limited disease like that under present consideration.

Pneumonia is an infection that may exhaust itself within twenty-four hours, or it may prevail into the second week, and, granting the prodromes of exudation, it cannot be averted, and, once started, it cannot be arrested artificially; moreover, it is for the best interests of the patient's future welfare to refrain from such futile endeavors. While we cannot say positively that something may not be discovered that will neutralize the toxic products of the pneumococcus, or check its future germination, without being equally or almost as injurious to the patient, still many experiments in this direction are, considering the natural history of the infection and the ultimate well-being of the person affected, superfluous, if not absolutely pernicious in their consequences. Moreover, it is one of the objects of this paper to show that in all probability the rise of temperature in an infectious disease such as pneumonia, is not only an index of the activity of the process, but also one of nature's ways of safely inhibiting the growth and reproduction of the parasitic microorganisms. In pursuance of this question of treatment, Fagge[8] remarks that "For several years past the conviction has prevailed that, as a rule, no active interference with the natural course of the disease (pneumonia) is needed. The principal share in establishing this reform in practice on a sound basis of observation must be attributed to the late Dr. Hughes Bennett of Edinburgh." Likewise, Niemeyer[9] says, "Indeed, it has been proved that, unless warranted by special indications, actual interference has an unfavorable effect upon the course of pneumonia." Furthermore, William Osler[10] writes that "Pneumonia is a self-limited disease, which can neither be aborted nor cut short by any means at our command. Even under the most unfavorable circumstances it may terminate abruptly and naturally, without a dose of medicine having been administered."

Although there are now nine consecutive cases of acute pneumonia soon to be reported from my recent service of two months at the New York Post-Graduate Hospital[11] of varying degrees of intensity and of complications, in patients ranging in age from fifteen to sixty years, which were so fortunate as to recover under methods of treatment herein advocated, nevertheless it would be rash in the extreme for me to maintain that a second series necessarily would have a like favorable termination. These results, however, may be placed beside those which are marshalled in support of a different argument; otherwise they point to nothing, except, perhaps, a successful meeting of the arising incidents. If pneumonia is attended by expectoration, which is not always the case, the sputa should be invariably disinfected, and, moreover, since the specific germs of the disease are voided also by way of the bladder and the intestines, the urine and fæces should be subjected to a similar procedure.

With regard to the diet, there is more danger of over-feeding than of any lack of nourishment. Considering that the gastro-intestinal functions are deranged, it is only hurtful to add to the system extra burdens of digestion and assimilation. Small quantities of pure milk, either plain, diluted with vichy or else predigested, every two hours, possibly fortified now and then by the yolk of an egg, alternating with beef tea and various broths, such as barley broth in particular, is a regimen that has proved satisfactory. When a patient happens to be sleeping naturally, by the way, rather than disturb him, his food should be for the time being withheld. Water must not only be freely allowed, but also frequently urged upon the patient, for it is to be remembered that milk is food, though fluid, and is adequate neither to quench thirst or effectually to flush the system, an important proceeding when there is in the body an additional poison to be expelled.

The local applications to the chest for pneumonia, such as hot poultices, or flannel and oil-silk jackets, are useless, so far as the disease itself is concerned, but ice-bags, though not much employed by me, are by William Osler and others highly commended. Oxygen, in a limited way, may be of benefit if given early enough and well diluted by atmospheric air when administered. As a last resort, on the other hand, while it lessens the cyanosis and sometimes also the distress of the sufferer, it fails to save him notwithstanding. One is not infrequently led to reflect how many poor dying mortals are worried, if not tormented, during their last moments by the well intended but senseless endeavors of the friends and attendants to get them to swallow, despite their feeble protests, both food and medicine. It certainly would be more humane and dignified to allow those who are manifestly dying to pass quietly away without such persistent and futile annoyances. Aconite and its congeners are worse than useless, in pneumonia at any stage, for they are actually harmful; they depress the action of the heart and thereby produce one of the very things we desire to avoid, namely, internal capillary stagnation.

With respect to the use of the lancet in this affection, little can be said as a result of experience by the medical men of this generation. Its former abuse gave rise to a reaction that may possibly have gone too far in the opposite direction. This certainly is the belief expressed by Dr. Alfred Mercer[12] upon this theme in his able and interesting dissertation. While there are some instances of mechanical obstruction to the right side of the heart that would be, and probably formerly were, benefited by an abstraction of blood from the venous circulation, the chief danger with the heart, as referred to by me elsewhere, is an acute degeneration of its tissues, due to the toxins resulting from an infection by the diplococcus, which calls rather for stimulation. If, however, this degeneration is extensive, there will not be much reserve power left in the organ to be brought into action, even by stimulation. Bleeding, in accordance with my conclusions, in these days may now and then be of advantage, but at least the average city private or hospital patient needs all the blood within his body for future contingencies. The most urgent symptom at the beginning of this affection is the pleuritic pain, though it is not always in evidence. Should the ice-bag or hot poultice prove inadequate at this juncture, morphine or some form of opium is generally recommended. My experience leads me to advise dry cupping in preference, and not with toy cups, but with a large common tumbler, which is usually effective. In regard to opiates, they should seldom be given, and never in large doses, to a patient suffering from pneumonia. Restlessness and even moderate suffering had better be endured for a few hours if it cannot be relieved otherwise, than to arrest or even diminish excretion, especially of the kidneys, which is exactly what drugs of this nature do, except in relation to the skin, to a greater or less extent invariably. Inasmuch as the kidneys are the chief eliminators of poisonous material collected in the system, and as they are often inactive in this malady, a drug that has a tendency to further check this function, such as opium, is and must be detrimental. Bouchard[13] says, "when we studied the toxic properties of urine in pneumonia in six cases, we found at once that it is more poisonous than normal urine; it is capable of killing in the proportion of nineteen cubic centimeters per kilogram of the animal, as a minimum, the average proportion being 38 cubic centimeters." Finally, patients ill with pneumonia, and more especially those of advanced age, now and then get a well intended relatively large dose of morphine, that produces comfort and quietude without doubt, but which at the same time, unfortunately, robs them of the few remaining fighting chances for life.

In the minds of a certain number of physicians an elevation of temperature seems to be something that must be lowered at all hazards; whereas, in reality it is one of the natural expressions of an infection, and short of well-defined hyperpyrexia, which is possibly a virtue in excess and therefore vicious, it is not harmful, but on the contrary advantageous. Bouchard[14] quotes that "Riess, experimenting upon animals suffering from infectious diseases, lowers their temperature artificially until they become normal; but the disease continues and death ensues." Although high fever in pneumonia reveals an extensive infection, still it equally reveals a power on the part of the patient to react to the poison. Fever of a moderate degree, on the other hand, indicates two quite different things, namely, a corresponding moderate infection or else an inability to react, such as we often see in secondary and terminal pneumonias. Lenhartz[15] teaches that, "the so-called pathogenic bacteria, which are recognized as the exciters of the infectious diseases, thrive best at the temperature of the body, while the non-pathogenic grow best at a far lower temperature." Hence the exceeding likelihood that an elevation above the normal body temperature tends to inhibit the growth of the parasitic pneumococcus. Bouchard[16] asks, "Can fever help the system to free itself from the infectious organisms?" and then continues, "we know that certain microbes cannot live beyond certain temperatures which do not kill a human being. The bacteria of malignant pustule, which cannot live in a temperature higher than 104° F, have no effect on birds, their normal temperature being above that point. Pasteur has shown that it is necessary to cool a fowl in order to render it able to contract this disease. This experimental argument is brought forward to show that the elevation of the temperature of the body in fever creates a physical medium that is unfavorable to the infectious organism."

Speaking of the fatty degeneration of the cardiac muscles in a dog subjected to a gradual elevation of temperature, until it reached 111.2° F. with a fatal termination, Bouchard[17] says, "I was led to think that the excessive elevation of temperature was the cause of the fatty degeneration, but Naunyn and Rosenthal found that no similar effect was produced in animals at the excessive temperatures observed in man suffering from disease." These same experimenters were able to keep rabbits alive for weeks ranging between 105.8° F. and 109.5° F. without ill effects being observed. "Excessive elevation of temperature," concludes Bouchard,[8] "is therefore not a source of danger from the point of view of anatomical lesion or from the point of view of denutrition. We may say, therefore, that it indicates the gravity of the disease but does not cause it. Elevation of temperature announces but does not constitute the danger." Consequently, if the action of heat upon the heart muscles of the lower animals is comparable to what takes place in the human heart under like conditions, these experiments tend to show that there is certainly no danger from a short exposure to high fever in mankind. These foregoing quotations have been made at some length, because they bear out what has long been my conviction in regard to the fever of infection. My experience is that the cold sponge bath is generally helpful in case of nervous symptoms, and withal more or less of a stimulant, as well as a promoter of the secretions, but, as a rule, it is not so effective in pneumonia as in typhoid fever. The temperature for six days in one of the nine patients previously mentioned is here included, as several points of more than passing interest are involved. In the first place the fever was high, the infection being intense, and there was acute nephritis, but the patient reacted well and recovered. Moreover, neither the temperature nor the nervous symptoms were affected by such regular bathing as commonly influences typhoid fever. Lastly, by means of the subcutaneous introduction of 500 c.m.^{3} of a physiological saline solution, there was a temporary amelioration of symptoms, which probably would have been sustained by increase of elimination had that procedure been repeated. Furthermore, it is instructive to record that the white blood count at the time of highest fever was but 9,000 to the cubic millimeter. The temperature taken at frequent intervals is as follows: January 26, 6 A.M., 104.4° F., 9 A.M., 104; 12 M., 104; 3 P.M., 104.2; 6 P.M., 104; 9 P.M., 104; 12 M., 104.4. January 27, 3 A.M., 105.4; 3.45 A.M., 105.4; 6 A.M., 105, 9 A.M., 105.4; 10.30 A.M., 105.2; 12 M., 105.4; 3 P.M., 105.6; 6 P.M., 105, 7.30 P.M., 104.1; 9 P.M., 105, 4.30 P.M., 105; 11 P.M., 105.4; January 28, 1 A.M., 105.4; 1.30 A.M., 105.2; 3 A.M., 105, 3.30 A.M., 105; 5 A.M., 105.2; 5.30 A.M., 104.6; 6 A.M., 104.6, 7.30 A.M., 105; 9.30 A.M., 104.6; 11.30 A.M., 104.2; 12 M., 104.6; 1 P.M., 104.8; 3.30 P.M., 104.8; 5.30 P.M., 104.8, 6 P.M., 104. At this juncture 500 c.m.^{3} of a physiological saline solution were given hypodermically in the right flank. Here he became rational, and his temperature in the course of three days gradually reached normal. The great question in respect to the treatment of pneumonia centers about the heart of the patient. Acute degenerative changes in the cardiac muscles, due chiefly to the infective process, are prone to disable this organ and precipitate venous stasis and œdema of the lungs, which, if considerable, are serious complications. Pulmonary œdema calls for energetic dry cupping as well as for thorough stimulation. A good way to maintain the integrity of the heart is not to begin at once to goad it by stimulants simply because the patient has pneumonia. Alcohol in the form of pure whiskey, or brandy in small or moderate doses, rather as a food, and for the saving of strength than as a stimulant, seems usually beneficial. Ammonia, strychnia, caffein and nitroglycerin are valuable, but at least in large doses, they must be reserved to arouse latent energy in emergencies. Too hard a preliminary run for a horse may find his muscles unequal to the supreme effort of taking a hurdle.

Digitalis is not a favorite remedy with me in pneumonia unless there is a previous valvular disease. It may be used with caution, and should be stopped if the function of the kidneys is thereby decreased, for one of the troubles of pneumonia is renal inactivity. Potassium acetate or potassium iodide largely diluted, should be given when the kidneys are working sluggishly. Large doses of ammonia, of alcohol, and especially of strychnia, have turned the scale in favor of recovery when the pulmonary second sound was waning in force and things, in general, were unpropitious. Defervescence is not uncommonly a trying period in pneumonia, and, because of the previous inroads made upon the heart, calls for stimulation and, moreover, for caution in the getting-up of the patient. In one of my series of patients that was handicapped by a mitral stenosis, a grave complication in an older person, the heart, which was temporarily much disturbed, was set right by digitalis and, owing to her youth, despite a double pneumonia and pleurisy with a small serous effusion, she recovered. The diplococcus pneumoniæ, by the way, was found in the serum taken from the pleural cavity by aspiration.

It has become a custom in my hospital service to preface all other medication in this disease by 1-10 gr. doses of calomel every fifteen minutes until one grain has been taken, followed by magnesia sulphate, in the form of a syrup of lemon compound. This is seldom contraindicated, and it frees the intestinal tract from the existing products of fermentation. Another of these patients came with the previous history of alcoholism, and she was at once, for obvious reasons, put upon regular and fairly large doses of whiskey. Still another appeared with the opium habit, and we were obliged for a time to include this drug in small doses in the treatment. One of the series of patients, forty years of age, had apical pneumonia, but with little fever and no delirium. Another had phlebitis of the femoral vein following the lung lesion. Finally, there were two cases among this number that were interesting as examples of the good results of hypodermoclysis. The first patient, who had single pneumonia complicated by an acute nephritis, arrived at defervescence with a dry, brown tongue, and somnolence, alternating with wild delirium. His urine, in spite of various therapeutic endeavors, was but sixteen ounces in the twenty-four hours. He was, thereupon, given a subcutaneous physiological salt infusion of 440 c.m.^{3} in his right flank, and the next twenty-four hours found him with a moist tongue, clear mind and voiding 46 ounces of urine. The following three days there were 58, 45 and 48 ounces of urine passed respectively; his recovery was thenceforth uninterrupted. The second patient likewise had acute nephritis, but with double pneumonia. On the day of crisis he had a dry, brown tongue, and was wildly delirious. His urine amounted to only 16 or 17 ounces in the twenty-four hours. Hypodermoclysis of 400 c.m.^{3}, of a similar saline solution, increased the action of his kidneys to 43 ounces in the succeeding twenty-four hours, his delirium disappeared, his tongue grew moist, and thereupon he became convalescent.

Recapitulation.—To condense what the foregoing thesis endeavors to explain and to maintain, pneumonia primarily owes its shortness and self-limitation to the perishability of its micro-parasite; the type of the disease depends upon the condition of the individual; pneumonia simply as pneumonia requires no interference; diplococci thrive best at the normal human temperature; fever inhibits the growth of the parasite and is therefore beneficial; high fever indicates extensive infection, meantime varying degrees of reactive ability; low fever either inability to react or else moderate infection; specific medication is unnecessary in pneumonia, if not pernicious; it is imperative to disinfect dejecta and expectoration; aconite and its congeners are injurious; bleeding is seldom required; opium, checking renal activity, in large doses is contraindicated; in old persons opium is exceedingly dangerous; oxygen is useful but not indispensable; alcohol is valuable as food, and it conserves energy; strychnia, ammonia, alcohol and nitroglycerin in large doses, as stimulants, should be reserved for emergencies; subcutaneous infusion of a physiological saline solution is invaluable for renal elimination of poisonous accumulations; last, though not least, specific remedies at best are but makeshifts, prevention of infection is the *desideratum.*

The Restriction of Scarlet Fever.—Guy L. Kiefer thus sums up the most important rules which the local health officer should enforce, in the order of their importance: (1) A thorough medical inspection of the schools; (2) Isolation of the patient in a hospital, if possible, followed by immediate disinfection of the premises and of all persons who have been exposed, and a careful daily inspection of such persons; (3) Isolation of the patient at his home, whenever transfer to the hospital is impracticable. Strict quarantine of the house for a period equal to the duration of the disease, but never shorter than the maximum period of incubation; (4) The employment of guards to enforce quarantine; (5) Thorough disinfection with formaldehyde of the house and its contents before quarantine is raised; (6) Thorough investigation into the possible source of infection of each individual case.—*The Physician and Surgeon.*

QUESTIONS OF PRIORITY IN THE SURGICAL TREATMENT OF CHRONIC BRIGHT'S DISEASE.

By GEORGE M. EDEBOHLS, M.D.,
NEW YORK.

Under the heading "The Cure of Chronic Bright's Disease by Operation," the Medical Record of March 22, 1902, contains, on page 467, a communication from Dr. A. Rose, the purpose of which, as enunciated in the concluding sentence, is to prove "that Edebohls was *not* the first who introduced the cure of chronic Bright's disease by operation." This is as far as Dr. Rose's sense of the historical proprieties carries him. He does *not* tell us *who* was the first to propose, and *who* was the first to perform operation upon the kidneys for the deliberate purpose of curing chronic Bright's disease. Instead, he cites, in a loose and general way, five medical writers, and makes the charge that I overlooked their claims, or rather the claims alleged for them by Dr. Rose, to priority in the matter. In making this charge Dr. Rose tells the truth as far as he goes, but fails to go far enough, and to tell the whole truth, as I hope to show farther on.

In simple justice to myself, I cannot remain silent under the accusations of Dr. Rose, lest my silence be misconstrued as an admission of the correctness of his charges. With an apology for the necessarily obtrusive personal character of what I shall have to say, I will plunge at once *in medias res.*

My priority claims in relation to the surgical treatment of chronic Bright's disease may be summarized as follows:

(*a*). I was the first to observe and to publish the curative effects of nephropexy upon kidneys affected with chronic Bright's disease.

(*b*). I was the first to undertake an operation upon the kidneys with the deliberate object in view of bringing about a cure of a previously diagnosticated chronic Bright's disease.

(*c*). I was the first to propose to treat chronic Bright's disease *as such* by operation upon the kidneys.

(*d*). I was the first to propose, the first to perform, and the first to report renal decapsulation for chronic Bright's disease.

(*e*). I was the first to publish a larger number of operations upon kidneys undertaken for the purpose of bringing about a cure of chronic Bright's disease.

The various communications bearing more or less directly upon the questions at issue, which have appeared from time to time, including those of all the authors cited by Dr. Rose, as well as those of one or two writers not mentioned by him, will be found enumerated in their order of publication at the end of this article. In my review of these communications, and in the further discussion of the subject, I will, as a matter of convenience and brevity, refer to these publications by number.

(1) Harrison. This publication is, perhaps, the most widely known and the most frequently quoted of those relating in any manner to the subject. It is specifically cited by Rose as one of the articles which he charges I have overlooked. That I have neither overlooked it nor failed to quote it correctly in its proper place will be shown under (15).

Harrison writes:—"Since the introduction of the more general adoption of direct exploration of the kidney through an incision from the loin or otherwise, a certain proportion of cases have been met with where it failed to reveal any obvious cause for the symptom or symptoms which led to the adoption of the proceeding. It has, however, been frequently noticed that such cases were often completely and permanently cured by what was done. American surgery. Annandale was one of the first to draw attention to this fact."

Following this introduction of the subject, Harrison details three cases of his own presenting acute renal symptoms in which he undertook exploratory nephrotomy, either upon an erroneous diagnosis or without having reached a positive diagnosis, and in which the symptoms disappeared as a result of the surgical intervention. He writes: "Looking back at the three cases I have briefly related I believe that the first was scarlatinal nephritis, the second nephritis from exposure to cold and damp, and the last subacute nephritis following most probably upon influenza."

Harrison believes that the good results obtained in his cases were due to the relief of renal tension by incision or puncture of the kidney, or of its capsule, or of both. This constitutes a decided amplification and very material extension of an idea expressed a number of years previously by our own countryman, L. McLane Tiffany, in a paper entitled "Free Division of the Capsule of the Kidney for the Relief of Nephralgia" (*Annals of Surgery*, August, 1889, 104-118). Tiffany writes: "It appeared to me likely that, from one cause or another, swelling of an irritated kidney might occur, which swelling being resisted by the capsule, could induce a sensation of pain." And again: "Division of the capsule of the kidney at once suggested itself as a therapeutic measure in nephritic colic." In reporting the history of his case Tiffany goes on to say:—"The capsule of the kidney was then freely slit open for a distance of three inches or more, the incision passing by the side of the deep scar referred to. The edges of the cut capsule gaped widely, which I considered evidence that tension had existed."

(2) Newman. The nature of Newman's cases and the indications upon which operation was undertaken are sufficiently evident from the title, and are tersely stated by Newman himself. He describes "four cases, in two of which he performed nephrorrhaphy for the cure of transitory hydronephrosis, and two other cases in which the same operation was resorted to for the relief of torsion of the renal bloodvessels, causing albuminuria and the presence of tube casts in the urine." They are not claimed by Newman as cases of chronic nephritis, but are cited as illustrating the transient congestive effects of intermittent hydronephrosis and partial strangulation upon a movable kidney, effects already well known, chiefly through the writings of Dietl, in 1864, and of Landau, in 1881.

(3) Harrison, in this paper, repeats his three cases already detailed in (1), gives an additional case of Hoeber, and cites Newman's two cases outlined in (2). He proposes incision in acute suppression of urine and in acute nephritis with tenderness on pressure over kidney and slow disappearance of casts and albumen.

(4) Wolff. One of Edmund Rose's cases, detailed by Wolff, is cited specifically by Dr. Achilles Rose, as proving that Edebohls was not the first "who discovered the effect of nephropexy on the kidney affected with Bright's disease." Dr. A. Rose quotes from Mongour (18):—"In Rose's case especially the kidney was effected by well-marked chronic nephritis, and the urine, examined several years after the nephropexy, revealed absolutely no signs of renal lesion." Unfortunately for Dr. A. Rose, Mongour (18) evidently quoted from my own paper (15), where is stated, on page 969: "One practically identical observation is recorded by Wolff as following a nephropexy performed by Rose. At the operation the kidney was found to be the seat of well-marked chronic nephritis, while an examination of the urine made several years later showed both kidneys to be healthy." Karo (16), in translating my article (15) into German, adds a footnote on page 82, to the following effect: "Edebohls has not understood Wolff correctly. Wolff simply mentions that the kidney was atrophic; there is no mention of nephritis. On admission the urine was 'slightly turbid, free from albumin.'" On again consulting Wolff's publication I find that Karo is correct, and that I originally misunderstood Wolff. My apologies are due to Dr. Rose for having, though unintentionally and only mediately through Mongour (18), led him into error, though why Dr. Rose preferred to quote at second hand from Mongour's publication in a foreign tongue, rather than from my own prior publication (15) in English, still remains to be explained.

The case in question of E. Rose, reported by Wolff, was operated upon on January 14, 1896. So that even if it had been a case of nephropexy upon a movable kidney affected by chronic nephritis, *which it was not*, it was antedated by four similar operations of my own which a reference to (5) will show to have been performed on November 29, 1892; March 10, 1893; May 11, 1893, and January 11, 1896, respectively.

The foregoing, taken in connection with what I shall have to say under (5), seems to me to prove clearly my claim (*a*), that I was the first to observe and to publish the curative effects of nephropexy upon kidneys affected with chronic Bright's disease.

(5) Edebohls. The scope of this paper is clearly indicated by its title. In it I report six cases of nephropexy performed upon movable kidneys the seat of chronic nephritis. The favorable experiences as regards the permanent cure of the coexisting chronic Bright's disease obtained in Cases I, IV, and V, led me to operate upon Case VI with the deliberate object in view of favorably influencing or curing the chronic nephritis. To quote from the original: "The fortunate effects (*i. e.* the complete and permanent disappearance of albumin and casts from the urine) in three of these five cases influenced me to regard the chronic nephritis of the sixth as a new indication, additional to other well-recognized and admitted existing indications, of nephropexy for movable kidney." And again: "In view of the favorable results obtained in the cases already cited, bilateral nephropexy was advised, both to relieve the symptoms due to mobility of the kidney, and with the hope of favorably influencing the nephritis. Both kidneys were anchored and the uterus curetted, January 10, 1898." As a result of the operation, the patient was cured of her chronic Bright's disease and remains cured to this day. The concluding sentence of the paper reads: "My own favorable experience warrants me, for the present, in regarding chronic nephritis affecting a movable kidney as an important indication for nephropexy."

The above is presented in substantiation of claim (*b*), that I was the first to undertake an operation upon the kidneys with the deliberate purpose of bringing about a cure of a previously diagnosticated chronic Bright's disease, and of claim (*c*), that I was the first to propose to treat chronic Bright's disease as such by operation upon the kidneys.

It is from this paper that Dr. Rose quotes to show that I overlooked previous publications on the same subject. He does not add that, in reality, there was no previous literature on the subject of which this article treats: "Chronic nephritis affecting a movable kidney as an indication for nephropexy."

Nor does Dr. Rose add that in my subsequent publication (15), equally well known to him, I give full references to the writings of Harrison, Newman, Wolff as reporter of E. Rose's cases, and Ferguson. In making the charge, therefore, that I overlooked the publications of these writers, apart from the fact that Ferguson did not publish until after the appearance of my publication (5), Dr. Rose, as I have already stated, tells the truth as far as he goes, but fails to go far enough and to tell the whole truth.

(6) Ferguson. The tenor of Ferguson's communication is summed up as follows in Edebohls (15), from which I take the liberty to quote: "Ferguson operated upon two kidneys, in the first of which 'no diagnosis was made, but a stone in the kidney was suspected and exploration advised,' while in the second, operation was undertaken upon the diagnosis of 'septic kidney.' On operation, both proved to be uncomplicated cases of acute or subacute nephritis. Nephropexy was performed upon both patients, and was followed by the prompt disappearance of albumin and casts from the urine. Ferguson's two patients were operated upon early in 1899. As a result of the outcome in both, though after a period of observation extending over a few months only, Ferguson, in June, 1899, seconded my proposition, made in April, 1899, to treat chronic Bright's disease surgically. Neither Ferguson's paper nor my own, however, has received much attention, and no other publications of the same tenor have come to my knowledge."

(7) Israel, in this important communication, details his own large personal experience in the surgical treatment of acute suppression of urine, renal colic and hæmaturia of renal origin, reporting fourteen operations with three deaths. As will be seen under (19), Israel resents the imputation of Senator that the tendency of this article is to lead to the surgical treatment of Bright's disease.

(8) Pousson. An industrious collection, from the literature, of twenty-five cases of nephrectomy and nephrotomy, including two nephrectomies and one nephrotomy followed by nephrectomy of his own, to illustrate, "le traitement chirurgical des certaines néphrites médicales." What Pousson understands under "néphrites médicales" is shown by his classification, which reads as follows:

1. Néphrites hématuriques	10 cases.
2. Néphrites compliquées de névralgie..	2 cases.
3. Néphrites infectieuses subaigueës, (under which heading he ranges the three cases of Harrison, (1)	4 cases.
4. Néphrites infectieuses aigueës	9 cases.

Pousson's own cases are a nephrectomy for hæmaturia, a nephrectomy for "anurie calculeuse gauche," and a nephrotomy, followed six months later by nephrectomy, for "nephrite hæmaturique unilaterale."

(9) Pousson. Essentially a lengthy detail of his case of nephrotomy followed by nephrectomy already quoted in (8). It leads up to

(10) Pousson. Essentially a selection from the cases already reported in (8), and their rearrangement, with the object of proving the existence of a reno-renal reflex and the rôle played by it in pathogeny.

It will, probably, be urged that the above publications of Pousson are scarcely pertinent to the subject of the surgical treatment of chronic Bright's disease. I have introduced them, however, because I wish to refer to them in the discussion of later articles by Pousson, whose claims to priority are specifically urged by Dr. Rose. What Pousson himself has to say regarding these claims will appear under (20).

(11) Edebohls. This paper contains the formal announcement of my proposition to treat surgically all cases of chronic Bright's disease. On page 691 we read: "I am now prepared to go a step farther and propose surgical intervention for the purpose of attempting a cure of chronic nephritis, whether the affected kidney be movable or in place. The surgical intervention, as in my practice heretofore, is to take the form of a nephropexy with denudation of the kidney cortex when the kidney is movable. When the inflamed kidney is not movable, and operative fixation of the organ is, therefore, not indicated, I shall content myself with entirely denuding the kidney of its capsule proper and thus affording free opportunity for the formation of new vascular connections, on a large scale, between the bloodvessels of the kidney and those of its fatty capsule. The relief to the kidney circulation by the establishment of an abundant collateral circulation, which, I believe, has been the chief factor in the production of the favorable results I have thus far obtained in the cure of Bright's disease affecting a movable kidney, will thus be applied to all chronically inflamed kidneys, whether movable or not."

(12) Pousson. The brief note here given reads as follows: "M. Pousson has operated also upon three cases of chronic nephritis, once for 'nephrite hæmaturique' and twice for uræmic accidents. In the first case extirpation of the kidney has brought about cessation of the hæmaturia and a permanent cure now lasting for three years. In the other two cases nephrotomy relieved transiently the uræmic accidents, which recurred, however, upon the healing of the renal incision. Subsequent removal of the kidney caused their disappearance in one of these patients."

Two of these cases, and possibly the third, have already been reported in other connections by Pousson (8), (9), (10). It is evident from the above account that there was no question of operation for the cure of chronic Bright's disease in any of these three cases, unless, indeed, extirpation of the kidney, which was performed in two cases, be accepted as a legitimate operation for the cure of chronic nephritis.

(13) Harrison repeats the histories of his three cases detailed in (1) and (3), and contributes three additional cases. The new cases are:

Case IV.—Nephrotomy for acute pain in a kidney, the seat of nephritis. Harrison thinks the incision prevented the nephritis from becoming chronic.

Case V.—Puncture of a kidney and its capsule for suppression of urine due to acute congestion, the result of injury.

Case VI.—Incision and drainage of a kidney, the seat of cystic degeneration.

The relief of renal tension by incision dominates this as well as Harrison's two previous communicacations (1) and (3). The character of the cases operated upon is clear from the outlines presented above.

(14) Pousson. The brief, and rather unsatisfactory, report states: "M. Pousson has been led to attribute the urinary disturbances of 'les brightiques' to an excess of tension and to combat them by nephrostomy." "He has practiced this operation in five cases of parenchymatous, interstitial or mixed nephritis." Three of these cases are detailed in (12), a reference to which will show that they were not operations for the cure of chronic Bright's disease, while a further reference to (20) will show that Pousson himself does not regard them as such.

"In each of these patients the author operated upon one kidney only, basing his choice upon certain vague indications." Operation was performed upon one kidney only, even though in three cases the inflammation involved both kidneys." One of the patients died within forty-eight hours after operation; four recovered.

(15) Edebohls. "This article contains a tabulated report of all my operations, to date of publication, upon the kidneys of patients suffering from chronic Bright's disease, together with a fuller description of my procedure of renal decapsulation for chronic Bright's disease. The contents of this paper are offered in evidence of the validity of claim (1), that I was the first to propose, the first to perform and the first to report a case of renal decapsulation for chronic Bright's disease, and of claim (2), that I was the first and, I may add, thus far the only one, to publish a larger number of operations upon kidneys undertaken for the purpose of bringing about a cure of chronic Bright's disease.

Twenty-eight kidneys, in all stages of chronic Bright's disease, were operated upon in nineteen patients. In fourteen of these nineteen patients operation was undertaken either for the sole purpose or for the purpose amongst others, of bringing about a cure of chronic Bright's disease. In eight patients cures of chronic Bright's disease, lasting at the time of report from one to over eight years after operation, were obtained."

(16) Edebohls. Karo's translation in full of (15) into German was the occasion of calling attention to the error into which Edebohls had fallen in relation to one of E. Rose's cases, as already set forth in (4).

(17) Pousson. "During the past three years Pousson has operated six 'brightiques,' and presents to the Society two patients, one of whom can be considered as cured."

The brief report is as meagre and unsatisfactory as (14). Three of the six patients are apparently those whose histories have already been repeatedly given and referred to by Pousson in (8), (9), (10), (12) and (14). That they were not operations undertaken for the cure of chronic Bright's disease has already been shown. The two patients presented were operated upon on July 3, 1901, and August 7, 1901, respectively. The date of operation of the sixth patient, who died within forty-eight hours after operation, is not given. Pousson himself, as will be seen under (20), does not claim that in any of these cases he operated for the cure of chronic Bright's disease as such.

(18) Mongour. This paper read apropos of Pousson's presentation of his two cases (17), deals, in general terms, with nephrotomy as an emergency operation in cases of chronic nephritis. In the course of some historical remarks Mongour says: "Encouraged by these facts, M. Pousson conceived the idea of practicing nephrotomy to remedy the grave and menacing accidents of chronic nephritis," which friendly imputation, however, Pousson gently denies in (21).

(19) Israel. Israel's position in the matter under discussion is clearly defined by himself in this his contribution to the rather warm discussion which followed the reading of Senator's paper on "Nierenkolik, Nierenblutung und Nephritis" before the Verein für innere Medicin in Berlin, on January 20, 1892. Israel writes: "As is apparent from what I have just said, I have never attempted to cure with the knife any form of nephritis whatsoever. *On the contrary, my intervention had for its sole object the removal of the distressing or dangerous symptoms of colic and profuse hemorrhages arising in connection with nephritis.*" And farther on we read: "I wish to correct another mistake of my friends as well as of my opponents. Many have thought that I sought to inaugurate an era of the surgical treatment of Bright's disease. Such has been far from being my intention."

(20) Pousson. In the discussion following the reading of a paper by Mongour (18), Pousson defines his own position in the development of the subject in the following extracts:—"My friend and colleague Mongour overdoes it when he ascribes to me the merit of having been the first to conceive the idea of interfering surgically in cases of chronic nephritis." "The most important contribution to this subject is that of Edebohls of New York." "It is plainly evident that l'interpretation d'Edebohls' is quite different from that which prompted Harrison's and my own operations." "Personally I have operated only when pressed by grave and well-nigh extreme symptoms; much less with the aim of curing my patients than of giving them a chance in the struggle against accidental complications which had resisted medical therapeutics." "For my own part, I cannot help being favorably impressed by the eighteen observations of Edebohls. That skilful and honorable surgeon can neither deceive himself nor wish to deceive us; the operation which he has recommended 'dans la periode d'état du mal de Bright' it appears to me should be imitated. Less bold than he, I have operated only under the pressure of grave accidental complications."

This finishes my review of the literature more or less pertinent to the subject of the operative treatment of chronic Bright's disease, a subject as yet in its infancy. True and accurate history, even though recent, is admittedly difficult to write, especially when the historian's self is involved. I have tried my best to be fair to others as well as to myself; as to how far I have succeeded I must leave to the reader to judge.

The position of each of the writers above cited on the question at issue, that of the surgical treatment of chronic Bright's disease, may be stated as follows.—

E. Rose, as reported by Wolff, is eliminated from the discussion by what has been shown under (4).

D. Newman's cases of hydronephrosis and strangulated movable kidney (3) were not cases of either acute or chronic nephritis, and have no bearing upon the subject of the surgical treatment of nephritis, either acute or chronic.

R. Harrison (1), (3), (13); A. H. Ferguson (6); J. Israel (7), (19); A. Pousson (8), (9), (10), (12), (14), (17), (20); and others cited by the two latter, each report instances of surgical interference in the course of acute, subacute or chronic nephritis, undertaken in some cases upon an erroneous diagnosis, in other cases to meet pressing indications, renal colic, hæmaturia, suppression of urine, etc., *never* with the deliberate object of bringing about a cure of chronic Bright's disease. Israel's (19) and Pousson's (20) own utterances state this fact emphatically.

Harrison, (1), (3), is the only one of the four writers mentioned who published prior to the appearance of my article (5), in which I first advocated the surgical treatment of chronic Bright's disease and detailed a case thus treated. Harrison describes his cases as cases of acute and subacute nephritis. The relief of renal tension by incision of the capsule or by nephrotomy dominates all his communications, and he considers that the good results obtained in his six cases were invariably due to its agency. This in itself shows the character of the cases treated by him. My own unpublished experience in a number of cases in which I operated upon the kidneys either for the relief of acute suppression of urine, for severe hæmaturia, or for enormous swelling due to acute nephritis, bears out the correctness of Harrison's explanation in acute cases and, in a great proportion at least, of acute exacerbations of chronic conditions. In none of the forty-six kidneys affected with *chronic* Bright's disease, however, which I have operated upon to date was there the least evidence of the existence of renal tension. To quote from my paper (15): "It is not a question of the simple relief of renal tension, the beneficial effects of which in acute conditions of the kidney, described by Harrison in 1896, have since been noted by an increasing number of surgeons. In these acute cases the tight fit of the capsule proper is manifest, and the kidney bulges at once through an incision or puncture made through the capsule. In chronic Bright's disease, on the contrary, the capsule proper, although it may be abnormally adherent to the kidney, never compresses the latter, and may even sit loosely upon it. Moreover, on cutting the capsule proper, the edges of the incision do not gap. It is interesting to note that Harrison, in his very recent communication, thinks that puncture to relieve renal tension in acute cases of nephritis may prevent them from advancing to the chronic stage." This extract from my paper is offered also in further refutation of the charge made by Dr. A. Rose that I overlooked the writings of Harrison.

The theory, therefore, on which my operation is based is, as pointed out by Pousson (20), quite different from that which prompted interference in Harrison's cases as well as his own. Nephrotomy for the relief of renal tension, and renal decapsulation for the purpose of creating new blood supplies for a kidney disabled by chronic Bright's disease are two quite different propositions.

The position of Ferguson, finally, has already been fully stated in my review of the only publication of Ferguson (6) bearing upon this subject which has come to my knowledge.

It is a matter of fact that nowhere in the literature, if we except my own report (5) of 1899, is there any record of an operation performed for the cure of chronic Bright's disease prior to the publication of my paper (15) in December, 1901. Moreover, in all the operations reported by Harrison, Newman, Ferguson, Israel, and Pousson, one kidney alone was operated upon, whereas an operation for the cure of chronic Bright's disease implies, in the very large majority of cases at least, an operation upon both kidneys. Of the twenty-nine patients with chronic Bright's disease upon whom I have thus far operated, one kidney was operated upon in four, both kidneys in twenty-five.

Israel (19), as we have seen, vehemently resents the imputation of desiring to bring about an era of surgical treatment of Bright's disease. Such an era seems, nevertheless, to have dawned, at least in America. Since the appearance of my article (15) in December last, one surgeon has published a case of operation for the cure of chronic Bright's disease, and I have incidentally learned of twelve additional unpublished cases operated upon by eleven different American surgeons, my operation of renal decapsulation having been performed in each instance. I have but little doubt that a considerably larger number of cases, of which I have not happened to hear, have at this writing been operated upon. Personally, I have since the publication of (15) performed bilateral renal decapsulation upon ten more sufferers from advanced chronic Bright's disease, two women, one female child, and seven men, two of the latter being physicians.

From all I can learn all these operations are the direct result of my initiative in the matter. Should disappointment follow the present effort to bring relief and hope of cure to a large number of sufferers from an otherwise incurable fatal malady, it is morally certain that a large share of the responsibility for such disappointment will be laid at my door. It is natural, therefore, and but human that I should not object to be the recipient of whatever credit the future may show to properly belong to the originator of the surgical treatment of chronic Bright's disease.

59 WEST FORTY-NINTH STREET, NEW YORK.

THE MODIFICATION OF BREAST-MILK BY MATERNAL DIET AND HYGIENE.

BY THOMAS S. SOUTHWORTH, M.D.,
NEW YORK.

[illegible]

In a former article the possibilities were presented of conserving the supply of maternal breast-milk in many cases in which it has been the custom to abandon it, and my justification for again presenting this subject must be found in further successful application of these principles and in the far-reaching and vital importance of the question.

I plead the cause of those infants who are deprived unnecessarily of their natural food, and consequently exposed to the insidious dangers so often encountered in the course of artificial feeding.

The great use of bottle feeding, of infant foods, of milk laboratories, home modifications and pure milk commissions, and no one more gladly welcomes the advances thus made than the writer, or is more ready to avail himself of all that is best in them when there is no other way of nourishing the child; but he would protest against their use when it is not necessary, and against the growing belief that they are just as safe as the mother's milk for the child.

It is easy to feed some children who will thrive on almost anything. Success in another group is only to be attained as the result of long experience and the most painstaking attention to details. But what of the remainder? These recruit the lists of the marasmics or fall victims to intercurrent disease, or if they survive are—not always it is true, but very often—the subjects of chronic digestive disturbances. Very many women who have no organic impediment to nursing lose their breast-milk early or furnish it in quantity or quality apparently unsuited to the needs of their infants, and eight out of ten of these babies are put upon the bottle for the lack of a little rational treatment of the mothers.

For the purpose of exemplifying this subject, one cannot do better than to relate the history of a fairly typical case.

On the 16th of July last, which was in the midst of a protracted hot term, I was called, in consultation by a colleague, to see a nursing infant five weeks old. Ever since its birth it had vomited and had disturbed stools. These latter had never been yellow. They were green, loose and frequent, varying of late from five to eleven in the twenty-four hours. For a considerable period the child's temperature had varied from 100 to 101° occasionally reaching 102° F. After a long trial of nursing alone, the quality of the maternal milk being under suspicion, a trial had been made of alternating the breast-feedings with a mixture of cream one part and water twelve parts, with no resulting improvement in vomiting or stools. The infant cried constantly night and day, drawing up its legs on the abdomen, passing considerable flatus and presenting the picture which is usually called colic. The character and frequency of the stools (5-11 per day) had naturally caused alarm, and bismuth and other remedies had been faithfully administered without material effect.

The nurse and family were worn out by constant attention to the baby night and day, the relations and circle of interested friends were becoming restless, and pressure was being brought to bear, as usual, upon the family physician to abandon the attempt to feed the child from the breast and to place it entirely upon some other food. To assist in deciding this question the consultation was determined upon.

In the face of this history, which is given as it was obtained at the time, all will doubtless agree that the outlook was not very favorable for a continuation of maternal nursing, and the circumstances of the family precluded the employment of a wet nurse. A careful physical examination of the child showed it to be in fair condition and revealed no organic disease. The mother proved to be a primipara, thirty-one years of age, of fairly good physique, with medium-sized breasts which seemed to contain sufficient milk. She was anemic and worn, but intelligent and interested. Her diet consisted of plain, sensible food, meat, a little coffee and no tea. In view of this interrogation of mother and child the case seemed clearly to be one of the class in which the mother's milk is said not to agree with the child—a class in which breast-feeding is usually abandoned when a wet-nurse is not obtainable.

Despite the five weeks of gastrointestinal disturbances at the breast, the opinion was expressed to the family physician that the mother could be made able to successfully nurse her child, and the following suggestions were made and transmitted by him to the mother: That artificial food and medicines should be stopped and the child nursed every two hours from 6 A.M. to 10 P.M. and during the night once at 2 A.M. That the mother, in addition to her usual sensible diet, drink a bowlful of corn meal gruel three times a day, continue to drink milk freely and substitute cracked cocoa for coffee. Instead of remaining all day in the house, she should begin to walk half a mile daily, and that this should be gradually extended to a mile or more, stopping short of fatigue. Iron should be taken after each meal and constipation relieved if it occurred. For the baby, lavage of the stomach once daily for the relief of the vomiting. An examination of the breast-milk showed a specific gravity of 1033 (normal 1031) and cream 2 per cent. Despite the low fat percentage, which tends to raise the specific gravity of the milk, this increase of specific gravity also suggests a proteid percentage higher than the normal.

July 20, four days later, the child was again seen. The stools continued frequent, green and watery. The temperature had once or twice reached 101° at night. Crying and vomiting continued as before. Iron had not as yet been given. Blaud's pills gr. v. were therefore begun.

July 26, six days later, the case was again carefully reviewed. The mother had found herself easily tired by walking, and had therefore been out but little. It was therefore suggested that she drive daily in the open air. The baby, which had thus far been carefully guarded in the house, was ordered to be kept upon the piazza as much as possible during the pleasant hours of the day.

July 30, after another period of four days, conditions had improved slightly. The temperature did not rise as high, the stools were less frequent, and the child was found to have gained 4 ounces. This served to encourage the mother, upon whom the evident anxiety of the nurse had reacted. As the nurse constantly picked up the child when it cried, it was suggested that she be dispensed with, and the child laid down after nursing and its crying disregarded.

August 3 (interval of four days), another gain of five ounces reported. Child had cried it out and now went to sleep when laid down. Vomits less, stools fewer and yellow. Mother's appearance decidedly improved.

August 9, child sleeps all night, waking for one nursing. Progress from this time on was steady and uneventful. Letters from the mother have reported: November 9, weight sixteen and one-half pounds; January 28, weight twenty-one pounds at seven months, baby well and breast milk abundant.

This case, so unpromising at the outset, has been related in full because it proved to be a complete vindication of the principle that the quality (and quantity) of maternal breast-milk is dependent upon the diet and hygiene of the mother, and that an apparently unsuitable secretion can be modified successfully by an intelligent attention to details. This principle is not a new one, but it has not as yet been adopted and put into practice by the profession.

This case had been faithfully and conscientiously managed, according to usually accepted methods. The mother had been brought safely through her puerperium, her diet was plain and nutritious, her bowels kept regular, the nursing hours wisely adjusted, and her anæmia not greater than that commonly seen after childbirth, yet the mother was not nursing the child successfully, and the majority of practitioners would, doubtless, have agreed that it was useless to continue the attempt. In fact, only a practical knowledge of the results obtained in a considerable series of similar cases, where the measures advocated had produced a satisfactory modification of the breast-milk, would have given the writer the confidence to urge their trial in this case.

The recommendations in this instance were neither intricate nor subtle. Regular hours and intervals of nursing, which are of the highest importance, and the neglect of which is at the bottom of many of the disturbances of infancy, had been duly arranged by the family physician, and required only an earnest endorsement. The liberal diet of plain nutritious food and cows' milk was continued; further fluid food, in the form of an abundance of thin well-cooked and salted yellow corn meal gruel, was added, and the suggestion offered that cocoa made from cracked cocoa be substituted for coffee. Had the quantity rather than the quality of the breast-milk been at fault, results, indicated by a larger flow of breast-milk, would have been experienced earlier, but here it was more a question of building up the mother's health, and this was not to be accomplished at once. In fact, you will recall that, owing to fatigue when walking was attempted, the mother secured little out-door exercise and fresh air until driving was begun on the tenth day. This fatigue was, doubtless, enhanced by the anæmia, the treatment of which by iron and laxatives was not begun until several days had elapsed. When these omissions were rectified, improvement began very promptly, as evidenced by gain in weight, improved stools and longer periods of sleep, and these became more marked as the child was carried out into the air and allowed to rest quietly without constant and insistent attention. The daily washings of the infant's stomach, which were begun for the purpose of allaying the vomiting, did not seem to influence this materially, but were continued during the doubtful period, partly as a placebo, in the absence of other direct treatment of the child.

In a paper read before the Medical Society of the County of New, York, in April, 1901*, I outlined the work which I had been carrying out for some time, both in hospital and dispensary practice, which has proved to me conclusively that a failing or faulty milk secretion may be restored by measures similar to those enumerated above, measures so simple that they could and should be put into practice by all physicians who are confronted by such situations. The analogy between the nursing mother and the dairy cow is a homely one, yet one which is readily grasped by the simplest mind. A large yield of good milk is rarely if ever produced by an animal in poor condition and improperly or unsuitably fed. There is distinct relationship recognized by all intelligent dairymen between the food and environment of the cattle and the quality of the milk. This has also been demonstrated experimentally in other mammals besides the cow. The time has arrived when, with the decreasing ability of the human female to suckle her young, owing to the influence of various factors in our modern life, this question should receive more general consideration and investigation, for the successful rearing of infants and a decrease in the mortality of those under one year of age is of the highest importance to the commonwealth as well as to the family and the individual. This is all the truer because the tendency among civilized nations is towards smaller families and the enhancing of the value of individual lives. The tendency is much too great, both among the laity and the profession, to accept the view that an increasing number of women cannot nurse their children and consequently artificial substitutes are advised without intelligent or, at best, after only half-hearted endeavor to make the breast milk sufficient or suitable for the child's needs. This tendency is increasing rapidly under the influence of the fallacious belief that children can be reared as successfully upon the various forms of substitute feeding as upon that provided and adapted by nature. That this is apparently true, in a relatively small proportion of cases, may for the moment be admitted, but it is not yet true, and may never be true of the great majority of bottle-fed infants. For these bottle-fed children are more liable and more exposed to digestive and other diseases than their nursing contemporaries, and that is so because their nutrition is, as a rule, actually if not apparently below that of the child at the breast. Let me give a concrete example:

A coachman who drove me during the summer told me that although his wife had nursed their first child, their second child, put upon the bottle on account of some acute illness of the mother, had done so well that he had refused to allow his wife to nurse their last baby, and that this one was also thriving well. My inquiry, however, elicited the information that while the oldest child, which had been nursed, was living, the first of these artificially-fed children had, unfortunately, died of whooping cough. It evidently did not occur to him to associate its death in any way with its nutrition. Two weeks after this conversation he told me that he had been summoned to the city to bury the baby who had succumbed to an attack of acute gastro-enteritis. It would have been cruel to suggest to him that he was, probably, personally responsible for its death.

Compare, if you will, the appearance of many of the bottle babies which you see about you in this city with that of a normal breast-fed child of the same age. Think back over your own knowledge of the fatalities among children that have been artificially fed. Consider the children of much larger growth of whom, when called to see them for later ills, you have secured the history that they were always delicate and hard to rear. You have learned in most of these cases, if you have inquired, that they were not nursed.

It would seem impossible for any one to follow any considerable group of children, either in or out of institutions, without being convinced that the diseases of infancy are more fatal in bottle-fed children. This is a too well recognized cause of gastro-intestinal disease to require any argument. But what of diphtheria, measles, whooping-cough and broncho-pneumonia? Although artificial feeding may be easy while these children are well it becomes infinitely more difficult when they are sick.

---

*A plea for the conservation of breast milk in whole or in part.—Medical Record, May 6, 1901.

The child, which was previously on the ragged edge, usually succumbs promptly. The fat but flabby baby melts away rapidly. It is well recognized that varying the grades of rachitis, often of so mild a degree as to be overlooked, are to be found in a majority of the bottle-fed children in large cities. It is understood that we are speaking of all classes together. If then there be an involvement of the pulmonary substance, the softer thorax and weaker muscles of such children are less able to withstand the strain thrown upon them by a respiratory rate of fifty, sixty, or even more, per minute, with the effort to maintain, with curtailed air space, the aeration of an already impoverished blood. These children are severely handicapped and less likely to survive the attack.

Shall we simply fold our hands in pious regret that these things be, and lay the blame on Providence, or shall we awaken to our duty of forestalling these accidents by measures which, when directed to the nutrition and health of the mothers, are distinctly, although perhaps remotely, life-saving for the children. These remote, but none the less real, dangers are not realized or duly weighed in deciding for and against early weaning.

The most common argument which is raised against the feasibility of this plan is that in the ranks of the wealthy and among women of highly nervous temperaments, who are under the pressure of social duties, many cannot nurse their children at all. This class, we must remember, is, however, limited. Many of them probably cannot nurse, but many others, doubtless, could if they were made to see and accept their duty. Few mothers would deliberately choose to subject their children to additional risks, however remote in point of time, if these facts were impressed upon them. The full co-operation of the mother is indispensable if we are to obtain satisfactory results in our efforts to build up and maintain the secretion of the mammary glands. The mother must be willing to sacrifice social dissipations and unsuitable food for the sake of her child. She must be willing to take rational exercise, abjure tea and be content to lead a placid, unruffled existence, eating such plain food and drinking such fluids as are suggested for her without reference to her special preferences. But it is not necessary that life should be made burdensome by monotony and confinement; this can be relieved by judicious management on the part of the physician and the use of one or more bottle feedings daily of properly adapted cow's milk, to allow for longer absences by the mother for the purpose of exercise and simple recreation.

The maternal duty to her offspring does not terminate with parturition, and the vast majority of women are willing to adapt themselves to the new conditions and welcome helpful suggestions to that end. The mother who nurses her child is a happier woman, and by nursing it, I believe, the bond of affection is, upon the side of the mother, materially strengthened.

47 West Fifty-sixth Street.

A Case of Scleroderma, Associated with Raynaud's Disease.—William Ewart lays especial stress on the treatment of this case, which resulted in steady and rapid improvement. The nutritional indication was the first to receive attention, and rest in bed and an easily digestible, liberal diet were ordered. Later the patient was allowed six ounces of port wine daily. Protection of the peripheral circulation next received care. The hands were oiled and covered with protecting gloves, each hand being kept night and day enclosed in a bag containing a hot-water bottle, surrounded with cotton wool. [illegible] through the habit of [illegible] with [illegible]. The oil used was a mixture of equal parts of [illegible] and olive oil, with a few drops of oil of eucalyptus. To influence the thickening and rigidity of the skin, massage, systematic and frequent, with oil, was applied at intervals to the arms and hands and to the upper part of the chest and back. Later, hypodermic and peripheral stimulants were given, skin massage stopped, and voluntary movements of fingers encouraged. Then, to remedy the deficiency of subcutaneous fat, a mixture of cod-liver oil and [illegible] whiskey were ordered nightly, but had to be [illegible] quantities to be tolerated and was later resumed. A three-grain pill [illegible] was given every other night to facilitate the digestion of the oil.—*Medical Press and Circular.*

Neurasthenia and Hysteria in Diseases of the Nose, Throat and Ears.—Among the conditions enumerated by E. B. Gleason are impairment, loss or perversion of the sense of smell, and disturbances of sensibility of the nasal mucosa. Anæsthetic areas are ordinarily continuous through the nasal vestibule with similar areas on the face. The pharyngeal mucosa is frequently affected, but is not commonly anæsthetic. There is often a sense of constriction and sensation of a foreign body. The aphonic voice of hysterical women is so common as to be familiar to most practitioners. It varies from nearly complete inability to phonate to a whispering voice easily understood, and which becomes normal, at least for the time being, as the result of any strong emotion or excitement. In such case the appearance of the larynx, as seen by the laryngoscope, varies somewhat. When the mirror is first introduced, the cords are usually seen to come together as the patient attempts to phonate, and under such circumstances the voice, for the time being, is normal. However, if the inspection is continued for some time, the movements of the cords during attempted phonation are often seen to be jerky and irregular, or the appearance simulates that of paresis of a laryngeal muscle or group of muscles.—*International Medical Magazine.*

The Function of the Appendix.—E. P. Hershey concludes from his study of the subject: (1) That the appendix is in no sense a vestigial organ. (2) It is an exceedingly important secretory organ, its secretion serving to prevent fecal impaction in the cecum. (3) We should at all times be thoroughly capable of drawing that fine distinction between therapeutic and surgical treatment that exists in all pathological conditions of the appendix, so that when we know the functionating power of the organ is irreparably gone we should recognize that we have a most threatening condition within the abdominal walls. (4) Proper prophylaxis and therapeusis would in very many cases obviate the necessity for surgical interference. (5) If this organ is still believed to be vestigial in character, it must be admitted that nature has beautifully adapted it to its needs.—*Denver Medical Times*, February, 1902.

Alcohol in Carbolic-Acid Poisoning.—A. C. McDonald reports the case of a young woman who had swallowed over an ounce of carbolic acid with suicidal intent. When seen ten minutes later she was in deep coma with imminent collapse. A tube was passed into the stomach, through which was introduced half a pint of alcohol. Strychnine was injected hypodermically. The alcohol was then pumped out and the same operation repeated three times in succession. This was followed by repeated flushings with warm water, after which four ounces of whiskey were introduced and allowed to remain. The tube was then removed. Brandy and nitroglycerin were given hypodermically, and in the course of six hours the patient was conscious. On the day following she appeared perfectly well, with the exception of a severe pharyngitis.—*Fort Wayne Medical Journal-Magazine.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, April 26, 1902.

LATENT PNEUMONIA.

SEVERAL diseases whose approach is insidious. and whose development is slow, give no particular signs to warrant apprehension of a fatal result, until the patient has arrived at a stage in which treatment is of little or of no avail. Maladies of this order are artheroma of the aorta and valves of the heart, cancerous growths in various parts of the body, degeneration of the liver and kidneys, and some other deadly affections.

But while complaints in which the symptoms are masked and the incubation and course whereof is long protracted, are well known to medical men, there occur in many instances acute affections which by their eccentric mode of advance are a source of mystification both to those around the patient and to the physician who is called in when too late to be of service.

Such are measles, typhoid fever, pneumonia, pericarditis, peritonitis, and inflammation of the serous membrane in other localities. Cases of this description are of the greatest possible interest to the medical jurisprudent.

Dr. Harvey Littlejohn, Lecturer on Medical Jurisprudence at Surgeons' Hall, Edinburgh, has contributed to the *Edinburgh Medical Journal* for April a lucid article on this phase of pneumonia, in reference chiefly to the standpoint of medical jurisprudence. He first draws attention to the fact that in cases of pneumonia which run this course, that not only are the symptoms usually heralding an attack of the disease absent, but that the person affected may go about in a state of apparent good health, and that the existence of advanced pneumonia will not necessarily shut out the possibility of death having occurred from natural causes.

In no inconsiderable number of these cases, says Dr. Littlejohn, the post-mortem examination enables us to determine that death was due to natural causes, by finding the presence of a chronic disease unsuspected during life, and which had not interfered with the ordinary occupations and habits of the patient.

Dr. Littlejohn summarizes the result of his observations as follows:

1. Pneumonia may be completely latent during its whole course.

2. The form of the disease most liable to be latent is basal lobar pneumonia.

3. Alcoholic apical pneumonia is rarely latent during its whole course.

4. The disease may be latent even though the whole of one lung, or a considerable portion of both lungs, is affected.

5. In latent pneumonia, sudden death most commonly occurs during the stage of grey hepatization.

6. The condition is practically confined to persons addicted to excessive alcoholic intemperance.

7. Complete consolidation of the whole of one lung is not inconsistent with a person having continued to lead an active life up to the time of death.

8. Latent pneumonia is most frequent as a cause of sudden death during the winter months.

9. It is most common after the age of forty and in the male sex.

10. The explanation of the "latency" is to be found in the quantity of alcohol consumed after the onset of the disease; first, in masking the ordinary signs and symptoms by dulling sensibility, second by its stimulating effect, thus enabling a person to go about until he suddenly collapses and dies.

11. In medico-legal cases, the discovery of latent pneumonia may satisfactorily explain the death of an individual, and thus allay all suspicion connected with the case.

12. On the other hand, the existence of pneumonia, even in an advanced stage, will not preclude the possibility of an individual having died from other causes, natural or violent, and of his having been at the time of receiving an injury in a state of apparent good health. These conclusions will probably be accepted by physicians as, in the main, justified by their own observations, and from the medical jurisprudent's point of view be deemed worthy of serious consideration. Medical expert testimony in this country has for long been made the target for much invidious criticism, but when it is recognized that in a disease like pneumonia no characteristic symptoms may reveal themselves until the sufferer is almost at the point of death, then a fairer conception of the difficulties in the path of the medical witness will be had by the general public.

The larger number of medico-legal investigations—according to Dr. Littlejohn—and few will be found to controvert his statement—relate to cases of sudden or violent death, connected with which are often suspicious circumstances, tending to incriminate others. The forces of the law are put in action, and medical experts are retained by either side to give testimony. What wonder then if, for example, in a case of sudden death from latent pneumonia, in which foul play is suspected, the evidence of the medical experts should be of a seemingly conflicting character.

Unprejudiced reflection on the part of outsiders with regard to the probability of such occurrences might lead them to regard the medical witness with somewhat less prejudice, and not, as is too often the case now, to incontinently and unhesitatingly denounce him as a man willing to perjure himself for the sake of gain.

A New City Hospital.—Governor Odell has signed a bill authorizing the construction of a new hospital in the Borough of The Bronx, New York City. It directs the Sinking Fund Commission of the city to have bonds issued for $200,000 to be used in acquiring the site for the proposed structure, and for $300,000 for erecting and equipping the building.

QUARANTINE FOR YELLOW FEVER.

Dr. Alvah H. Doty, Health Officer of the Port of New York, will within the next two weeks go to Washington to discuss with Federal officials the subject of quarantine regulations, especially as they bear on yellow fever. He will, it is further stated, seek also that the Government do all in its power to bring about a conference of leading sanitarians who have dealt with the fever, looking to a modification of the existing quarantine regulations.

This is certainly a wise action on the part of Dr. Doty, and it is to be hoped that he will succeed in his object, for such a conference should have the effect of gathering the opinions of those experienced in the disease, and tend to settle the question as to whether the majority of experts believe in a radical alteration in the existing quarantine regulations, in their modification, or in leaving matters in statu quo.

Dr. Doty himself argues that as the mosquito is the only known medium of infection, quarantine regulations should be constructed from the mosquito standpoint alone. Thus Dr. Doty maintains that, when a ship upon which yellow fever has manifested itself is more than five days from the port of departure, removal of those infected removes the fever from the ship, provided that there are no mosquitoes aboard. The Health Officer of the Port of New York is an adherent of the theory that the mosquito is the only mode by which yellow fever infection is spread, and consequently thinks that the quarantine regulations now in force are unduly rigorous. He vigorously combats the view—up to recent times held by most sanitarians and still maintained by many scientific observers—that fomites have any influence on the spread of yellow fever, and therefore opposes disinfection.

The quarantine rules necessary in Dr. Doty's opinion, and which were embodied in his address delivered before the American Public Health Association, are worded as follows:

"The treatment of incoming vessels from ports infected with yellow fever becomes very simple: if they are five days or more in transit, and all on board are found to be well after a careful inspection and the use of the clinical thermometer, the vessel, its passengers and crew shall be released without further detention or treatment. If the vessel has been less than five days in transit, all on board who cannot present satisfactory evidence of immunity should be removed and held for examination until the completion of a period of five days from the time of departure from the infected port, and then released only after a careful inspection. When yellow fever is found on incoming vessels, the procedure should differ only so far as it concerns the removal of the patient to a properly constructed hospital or apartment for treatment. . . . If the future shows that there are other means of infection, it will then be time enough to add whatever restrictions are necessary for the protection of the public health."

Assuredly, the regulations as now framed are troublesome and, to a great extent, cripple, commerce, and are, perhaps, too vigorous. Nevertheless it must be borne in mind that a large number of experienced medical men, both in this country and elsewhere, are not yet convinced that the mosquito is the sole conveyer of the infection of yellow fever.

If, however, Dr. Doty can prevail upon the Government to bring about a conference of leading authorities on the subject, and the majority of these should decide that yellow fever can only be transmitted by mosquitoes, it will then have been demonstrated in a more or less conclusive manner that the existing quarantine regulations are superfluous, and their modification will follow as a matter of course.

UNCULTURED MEDICAL STUDENTS.

The question as to whether a physician requires polish and culture in order to make his way successfully in the profession, is one that has often been raised, but never decided in an entirely satisfactory manner. There are so many points which must be taken into account when considering the matter, that to assert dogmatically that the medical man should be an individual of wide knowledge and correct manners, would be to make a statement which does not apply to all members of the calling, wherever situated. But before discussing the subject further, it will be as well to refer to an article which appeared in the *Columbia Literary Monthly*, for March, and which, indeed, has given rise to these remarks.

An editorial in that magazine bluntly declares, without beating about the bush, that the greater part of the medical students in the Columbia College are not only uncultured but frequently even uncouth, and contend that only students having the Bachelor of Arts degree should be permitted to enter the Columbia School of Medicine, premising that such a procedure would exclude the boorish and unrefined. In support of this view the fact is pointed out that at Harvard and Johns Hopkins the possession of a degree in arts is necessary to enter upon the study of medicine.

The editorial in the *Columbia Monthly* sums up as follows:

"The place of the Bachelor of Arts in social and intellectual circles of life to-day is an interesting one to note. His era is at hand. What has thus far been accomplished in the world has been accomplished without him, what remains to be accomplished will be done by him, and with more directness and speed than results of the past have been obtained. His starting point is the goal others have striven for. As one in such a position he has an advantage over his unschooled brothers, but when working together with these he, in turn, also labors against obstacles.

"The science of medicine is founded upon broad principles, which should be understood before medicine itself is undertaken as a study. The college is the proper place to learn these truths. In medical schools tributary brooks and streams of knowledge should have already been left far behind, and the true current of work should take us with it from the outset. At the College of Physicians and Surgeons those who have made the correct start are retarded by those who have not, while the latter are at a disadvantage when compared with their fellows. This tends to a want of balance.

"Leaving aside, however, the question of fitness to do work, and turning to the wider sphere of the physician's effort, it must be admitted, to put it mildly, that culture and refinement are desirable in a doctor, and it must further be admitted that the greater part of the students at our medical schools are not only uncultured, but often even uncouth, thus being fundamentally unfit to become the highest type of their profession. A degree as the entrance requirement would go far to remedy this state. Unfortunately, many worthy men would thus be barred out, but the good resulting from such an injustice would far outweigh the injustice itself, and the benefit to the institution would be very great, although its number of students might be greatly diminished."

The foregoing quotations show that the writer of the article has, on the whole, grasped the right ideas, although his arguments contain some rather specious pleading and somewhat exaggerated notions with regard to the value of an A. B. degree.

In the first instance it is scarcely correct to say that the era of the man with an art degree has not yet come. In Germany and in Great Britain and in other countries of the European Continent he has arrived, and has already done great things in the professions—in a lesser degree in other branches of life.

However, the *Columbia Monthly*, perhaps, intended to confine its criticisms to the United States.

It must certainly be granted that opportunities of entering upon the study of the medical profession are too obviously easy in most parts of this country.

A youth desiring to become a doctor should, decidedly, possess a good general education, and should be well tested as to his acquirements in this respect before he is permitted to commence medical studies.

The day of the Bob Sawyer and Ben Allen type of medical student has passed never to return, and roughness of manner and coarseness of speech is no longer looked upon as the trade-mark of the medical man.

Nevertheless, although it must be conceded that a doctor is better in every way for a certain amount of polish and culture, would it not be carrying this view to too great lengths if in every medical school throughout the land the rule was made that a degree in arts must be had before medical studies could be commenced?

It must also be borne in mind that a degree in arts does not by any means necessarily confer culture, although it, undoubtedly, does tend to smooth the rough angles. In a university like Columbia, situated in the largest and richest city of the continent, the majority of whose medical graduates will presumably practice in New York or in some other large town, it would certainly seem eminently desirable that they, for their own sakes, should be men neither of uncultured nor of uncouth manners, and if the Columbia authorities are of the opinion that the most effective way of avoiding this state of affairs is to insist upon its medical students possessing a degree in arts, there can be no valid objection on the part of the general public to there views being carried into effect.

If such a course be decided upon, here is no reason why the subjects for the degree in arts should not include those which would be useful in the after medical studies, and not be wholly restricted to Latin, Greek, mathematics and the like.

The MEDICAL RECORD has always ardently advocated a raising of the standard of medical education throughout the country, and has, in particular, urged that the preliminary examinations in arts should be a fairly rigid criterion of a man's general knowledge.

THE NEW YORK BOARD OF HEALTH AND THE SALE OF THERAPEUTIC SERUMS.

A PETITION has recently been presented to the Mayor of New York City, protesting against the sale of antitoxin and vaccine virus as at present carried on by the Board of Health. The petitioners request that the Board should be granted such adequate appropriations as might be required for its legitimate needs, thus relieving it of the distasteful task of engaging in competition with regular trade, and setting its officials free to devote themselves to more congenial as well as more useful descriptions of work—as, for example, scientific research, the testing of sera, and the diffusion of useful information regarding sanitation.

The argument advanced by the Board in defence of its action is that more vaccine virus and antitoxin is produced than is actually required, and that under powers granted for the disposal of this surplus, two special funds were created, one known as the fund for gratuitous vaccination and the other as the antitoxin fund.

The petitioners contend that the application for the appropriations in the estimates gives a mistaken idea as to the amount which is expected to be expended, and that the Board, in a large measure, depends upon the income which it anticipates deriving from the antitoxin fund, for the proper continuance of the work of the department.

In short, it is claimed that the Board has taken advantage of the powers placed in its hands by the section of the Charter permitting the creation of the special funds to enter upon a policy of commercialism, to the detriment of private manufacturers, and in direct opposition to the principles upon which such bodies were founded.

It is impossible to resist the conviction that it would be to the best interests of the Board if it were to confine its operations to its legitimate sphere of action, and wholly purge itself of any suspicion of commercialism.

The City of New York is surely sufficiently rich and public spirited enough to provide the Board with ample appropriations for all the work which falls within its province, and, by so doing, will avoid the odium of seeming to allow a most important municipal department to be conducted upon commercial lines.

The assertion that by these methods alone the purity of therapeutic serums can be guaranteed will not bear close inspection, for any reputed failure on the part of manufacturers in these respects can be easily remedied by the appointment by Government or by State of a proper system of inspection.

It is right and fair that both vaccine and anti-

[illegible] should be freely distributed to those who cannot afford to buy these safeguards to health, but in selling such products at a cheap rate the ordinarily understood principles of just trading are [illegible].

STREET NOISES.

It is a moot question as to which of the cities of America—and incidentally of the world—is most afflicted with street noises. On this continent the race for the unenviable distinction is between New York and Chicago, and the partisans of each city believe apparently that its rival is the chief offender.

However, no one will deny that the conglomeration of sounds to be heard both by day and by night in New York is distinctly unpleasant, as well as being in a high degree detrimental to good health. A very considerable street noise is of course unavoidable, but many of the sounds by which the ears of the [illegible] residents of a large town are distressed, and their nerves racked, are wholly unnecessary.

The Betterment of London Association recognizing this fact, have recently presented a petition to the London County Council beseeching that body to take steps to mitigate the unbearable infliction of unnecessary street noises.

The London *Saturday Review* in commenting upon the action of the association and wishing it success in its efforts, points out that there are many obstacles in the way of the complete realization of the hopes of the quiet and nerve-tortured inhabitants. For example a habit is prevalent in London, which is also extremely common in certain parts of New York, that of elevated and hilarious youths and maidens making night hideous by their raucous rendering of popular songs of the day.

The writer in the *Saturday Review* rightly remarks that it is but seldom the policemen put a stop to the unmelodious strains of these disturbers of the peace, and gives as a probable reason that the policeman is little appreciative of the agony inflicted upon nervous people by such sounds, and that unnecessary noise is not to him any more than it is to the classes from whom he comes, an abomination [illegible] but in reality an exquisite form of enjoyment. Nevertheless when everything is said that can be said on the matter all rational inhabitants of towns will undoubtedly concur in agreeing that there are many street noises which are unnecessary and superfluous, and to suppress them would be for the good of the entire community.

LONGEVITY IN MODERN TIMES.

It is somewhat paradoxical to say that, in these times, which are frequently dubbed the age of degeneracy, the human life should be constantly lengthening its span. *The Standard* some time ago, made investigations into the question of present-day longevity, and as a result has published some instructive conclusions. In the seventeenth century mankind, throughout the civilized world, reached the meagre average age of thirteen years, while in Great Britain, at least at the present time, out of 1,000 people over 100 reach the age of seventy-five, thirty-eight reach eighty-five, and two attain to ninety-five; while one person in about every 5,000 becomes a centenarian, the general average being about thirty-eight.

According to the *Lancet*, the record for length of years is probably held by Michael Solis, who was living in Bogota in 1878, and who then claimed to be 184 years old. The case was thoroughly investigated in 1878, and the conclusion come to was that he was then 180. Solis was still living in 1878, so that if he died in that year he was 198 years of age.

Another remarkable instance of tenacity of life is afforded by Henry Jenkins of Bolton, Yorkshire, who was born in the year 1501, and who remained alive until 1669. This is also said to be a perfectly authentic instance.

Next in order came the celebrated Thomas Parr who was born in 1483 and died in 1635, at the age of 152.

Women, contrary to a general belief, do not reach the extreme ages sometimes attained by the male sex. The oldest woman living at present is probably Mrs. Nancy [illegible], a citizen of the United States, and a lady of color, who is now one hundred and twenty-one years of age. She lives in North Carolina.

A Hungarian lady celebrated, in 1894, the hundredth year of married life; this, it is needless to add, is a unique record. There is but a single instance of a marriage ceremony having taken place where both the contracting parties were centenarians. In 1772, according to the Parish register of Dublin, Pat Stephens, aged 109, being led to the altar Mrs. Berry, who was only seven years younger.

The soldier is, as a rule, a long-lived man, the hardships incidental to his career do not appear to shorten his days, or perhaps it is only a case of the survival of the fittest. Nevertheless the fact remains that the work-houses of Great Britain contain several old soldiers who are centenarians, and frequently retired officers far exceed the limit set by the Bible.

THE HOUSING PROBLEM.

At the third session of the American Academy of Political and Social Science, which opened in Philadelphia on April 4, the above subject was dealt with by several speakers.

Mr. Robert W. De Forest of New York spoke on "Tenement-house Legislation: Reasons for It; Its Proper Limitations;" Jane Addams of Hull House, Chicago, on "The Housing Problem in Chicago;" and Nathaniel B. Crenshaw of Philadelphia on "Certain Aspects of the Housing Situation in That City."

In all large cities of this country, as in every center of population throughout the world, the housing problem must be confronted to a greater or lesser degree. The difficulty presents itself in New York City in an especially acute form, and various schemes have been devised by philanthropists and sanitarians to provide the working poor with comfortable and at the same time healthy homes.

Model tenements have been planned, and in a few instances, constructed, by the benevolent, but, as pointed out by Mr. De Forest, while this is good as far as it goes, the benefits produced thereby are more than neutralized if other people not benevolent, who have no motive but gain for themselves, are permitted to build tenements which are not models. Therefore the first and foremost course to pursue, is to secure proper legislation, using that term, in its broadest sense, to include city ordinance as well as state law.

That builders only regard the matter from a commercial standpoint was clearly shown by the action of the Brooklyn builders in attempting to amend the existing Tenement bill to meet their views.

Such men ignore the principle of providing healthy habitations for the working classes, and care little for what may happen so long as money flows into their pockets. The defeat of the measure proposed by them was a notable victory for sanitary reformers, and should encourage the philanthropic citizens of other large cities to persevere in their efforts to ameliorate the lot of the immense army of tenement dwellers.

The Medical Record, in several articles, has dwelt upon the fact—only partially recognized by the majority of town dwellers—that a quantity of unsavory, ill-built, badly-ventilated tenement houses, the like of which are too common in New York, are a standing menace to the health of the inhabitants at large.

Tuberculosis and many other diseases will never be effectually stamped out until the disgracefully insanitary dwellings which cumber the ground in certain districts of New York are swept away, and in their stead buildings erected, fit for human beings to live in and not to merely exist.

Bacterial Investigations of the Water of Public Swimming Baths.

It is an undoubted fact that the water in many public swimming baths is frequently loaded with an immense quantity of bacteria.

Dr. R. G. Glynn, at the Liverpool Medical Institution, recently read a paper on the subject, in which were made these statements. He had directed his attention to the following points: (1) The total number of bacteria present in the water of the baths at the beginning and end of the day; (2) The number and nature of the pathogenic organisms present; and (3) The source of the organisms. Samples of water were taken in sterilized flasks and plated on agar within an hour after leaving the bath; these plates were incubated at 37° C., and the number of bacteria present in a cubic centimeter of the bath-water was estimated. The majority of the observations were made at baths which were filled with fresh water every morning. This water was practically sterile, containing less than three bacteria per cubic centimeter. An hour after the baths were opened the water gave forty-six bacteria per cubic centimeter; these were mainly derived from the air and the walls of the bath.

During the eight hours of the night the number of bacteria rose from three to forty-six per cubic centimeter. On five different occasions the examination of the water in the plunge bath at 9 P.M., during the months of June and July, gave an average of 4,676 bacteria per cubic centimeter, the average number of bathers being 292. A calculation, based on the capacity of the baths, showed that the water removed from the skin of each bather contained between 4,000,000,000 and 6,000 000,000 bacteria, excluding moulds and others which did not grow at 37° C.

With regard to the organisms discovered in the water, streptococci were never found and staphylococcus aureus and citreus very rarely; staphylococcus albus was abundant in three varieties—pyogenes albus, epidermidis albus, and cereus albus. At the end of the day bacillus coli was present in the bath to the number of eight per liter for each bather in first-class baths and forty-eight for each bather in the second class.

Dr. Glynn said that typhoid fever was probably never contracted in such baths as these, and the swallowing of water of the type analyzed was quite innocuous.

From time to time various complaints have been ascribed to infection in baths, but with doubtful accuracy, some who bathe constantly in the open complain of lassitude after swimming in a public bath; this should not be attributed to the quality of the water, but the temperature and defective ventilation of the bath-house itself. Public bath-houses, like all buildings in which large numbers of persons assemble, should be well ventilated and the temperature properly regulated.

Medical Nomenclature.

Many writers of the present day condemn the use of long-winded words in medical and surgical phraseology, and advance the plea for simpler and clearer language to illlustrate, verbally, scientific terms.

While there is much to be urged in favor of this contention, compound words derived from Greek or Latin are in many instances more or less esential to a correct comprehension of the condition or scientific definition thereby indicated. It would be impossible always to express by one Anglo-Saxon word a large number of medical, surgical, and scientific terms.

Nevertheless, there are undoubtedly occasions when Greek and Latin are abused in medical nomenclature.

The *Medical Magazine*, February, quotes from the *Ἰατρικὴ Πρόοδος* in support of this view.

The Greek journal discusses the question as follows:

"One of the most difficult and thorny tasks of a writer in the Hellenic tongue is the translation of medical terms and names which are published abroad by tens daily, and which claim for the most part a Greek origin, though they are far from obeying the rules of the language. The worst of it is that very many such terms have already been introduced into the universal language of science, and have become so usual, that their purgation or modification would be a gigantic and most difficult work. A Greek author or translator thus finds himself in a most awkward dilemma, and is at a loss what to do with such words; for the foreign publications not only include words of defective or of improper formation but, what is worse, monstrous and mongrel productions, one-half of Greek and the other half of Latin origin, such as the terms fluoroscope hæmoglobin, oxyhæmoglobin, Mesocæcum, caboluria, etc.

Science, January 24, contains an exceptionally able article on the custom of coining immensely long words of Greek or Latin origin, the majority, of which perhaps not only fail to accurately and lucidly denote the intended meaning, but tend to obfuscate the brains of readers by their obscurity.

Huxley—and Tyndall in a lesser degree—was a striking example of a scientific man who could clothe technical language in simple dress.

The writer in *Science* truly says, "There is yet another reason against the excessive use of Greek-English words, in particular. Greek is not a remnant of extinct geography, but an existing land with a very active people and a living language. The terms which paleontology has borrowed from the Greek may be returned by the Greeks to us, and, as Ruskin points out, "What you, in compliment to Greece, call a 'Dinotherium,' Greece, in compliment to you, must call a 'Nasty-beastium,' and you know the exchange of compliments can't last long."

This is in line with our previous quotation from the *Ἰατρικὴ Πρόοδος*.

Greek and Latin are necessary for the interchange of ideas among the scientific men of the world, but quite unnecessarily cumbersome and almost incomprehensible words have been coined with this object in view. The protest brought forward in *Science* is not against the use but the abuse in the manufacture and use of such words.

News of the Week.

An Ambulance Service for the Mount Sinai Hospital.—When the new buildings at Madison avenue and One Hundredth Street are taken possession of by the Mount Sinai Hospital, an ambulance service will be installed there. Hitherto, the hospital has been without such service. An offer has been made by several friends of the institution of two complete ambulances and a sum of money, the interest of which will provide for the maintenance of the service.

A Gift to the Saratoga Hospital.—A full [illegible] has been [illegible] for the Saratoga Hospital by Mrs. [illegible] of this city.

Pestilential Disease About Canton.—According to reports from the United States Consul at Canton, China, the country in the neighborhood of that city is being devastated by epidemic diseases. He says that whole villages on the banks of North River in the vicinity of [illegible] are depopulated by smallpox and typhoid. Fatshan, [illegible], a large town near Canton, is suffering from smallpox and plague.

The Annual Meeting of the Association of Military Surgeons of the United States, which will be held in Washington on June 5, 6, and 7, will have the largest attendance in the history of the organization. During the past year the membership of the association has increased by more than two hundred. An invitation has been extended to the armies of the world to be represented at the convention through their medical departments. A representative of the British army has been present at previous meetings, and this year in addition, delegates will be sent by France, Japan, and Mexico. Papers will also be forwarded from other countries, and the convention will thus assume an international character. The publication by the association of a journal devoted to military medicine, surgery, and hygiene, has done much to raise it in the estimation of foreign medico-military authorities.

Arrest of a "Nature Doctor."—A man named [illegible], who calls himself a "doctor," and who runs a "nature-cure" sanatorium in this city, has been arrested for practising medicine without a license. The immediate occasion of the inquiry into his methods and consequent arrest was the death in his house of a young girl who had been under his treatment.

The Use of Borax as a Meat Preservative.—Several wholesale meat dealers in St. Paul were recently arrested at the instigation of the retail dealers, and charged with using borax as a meat preservative. The evidence against them was conclusive, but through their attorneys they demurred to the charge and their cases were continued until April 29. A case similar to these is now pending in the Supreme Court of Minnesota, and it is expected that a decision will be had before the date of trial. The decision rests upon the point whether or not this use of borax is injurious to health.

Increase of Salary for Dr. Biggs.—The Board of Health of this city has raised the salary of Dr. Hermann M. Biggs from $2,500 to $5,000 per year, and changed his official title from Director of the Bacteriological Department to Medical Officer. His duties will be practically the same as heretofore.

Occupation for Epileptics under the City's Care.—Mr. Homer Folks, Charities Commissioner of New York City, has announced that he will put some of the more able-bodied epileptics and inmates of the Almshouse on Blackwell's Island on the Poor Farm on Staten Island, to help raise fresh vegetables for the city charitable institutions.

Trouble at the Mills' Training School.—The Board of Trustees of the Mills' Training School for Male Nurses at Bellevue Hospital lately passed an order assigning female supervisors to the training school, and placed them over the heads of the men who have held these positions. One female supervisor is placed over every two wards. The action, though the authorities of the school say, was simply for the purpose of enforcing discipline, caused great indignation among the students and the teachers. An agreement to resign in a body if the former conditions were not restored was signed by a large majority of the students, but not by those in the graduating class, and consequently the threat of a general strike could not be made effective.

Feeble-Minded Wards of the City.—Thirty feeble-minded children, formerly kept in the Kings County Almshouse, have been transferred to Randall's Island, where all feeble-minded children will be sent hereafter.

The Brooklyn College of Pharmacy.—Ground will soon be broken for the new Brooklyn College of Pharmacy, on Nostrand avenue between Clifton place and Lafayette avenue. The building will be fifty feet wide by ninety feet deep, three stories high. The basement will contain lockers, cloakroom, recreation rooms, etc. On the first floor will be a large lecture room with a seating capacity for 300 students. The main entrance will be in the center of the building, with the trustees' and clerks' rooms on either side of the hall. The second floor will be occupied entirely by the pharmaceutical and chemical laboratories, which will be provided with the most improved apparatus. There will be two quiz rooms on the third floor, which may be combined into an assembly hall.

Precaution Against Yellow Fever in Havana.—In his latest report on the health of Havana, Dr. Gorgas refers to the precautions taken to prevent the introduction of yellow fever into the now clean city. Acting on the belief that the disease is propagated only by mosquitoes, the Sanitary Department has put no restrictions upon goods, baggage, or fabrics of any kind coming from Vera Cruz or other infected ports. The only thing feared is that some person sick or about to become sick, with yellow fever may enter the city, thus poisoning the Havana mosquitoes. To avoid this, the Military Governor has issued an order requiring all non-immunes to report daily for examination, this examination being kept up during the period of incubation, in the case of each individual. There has been no case of yellow fever in the city for five months, and none of smallpox since July, 1900. It is satisfactory and reassuring to learn that Major Gorgas has been ordered to remain in Havana after the evacuation of Cuba by the United States troops, and continue his good work in preserving the city's health.

Cholera in the Philippines.—From the beginning of the epidemic up to April 21 there were 411 cases of cholera and 31[illegible] deaths in Manila, and 8[illegible]0 cases with 625 deaths in the provinces.

Work of the City Consumption Hospital.—The Commissioner of Charities recently gave out a statement of the results attained thus far at the phthisis hospital on Blackwell's Island opened on February 1. The whole number of patients admitted to the hospital to date has been 273. With few exceptions, all of the patients admitted were in more or less advanced stages of pulmonary tuberculosis. Of the 273 patients fifty-five have been discharged, fifty as improved and five not improved. The fifty patients who had improved, have, as a rule, either returned to their work or have gone to the country or the mountains at the suggestion of physicians. Twenty-eight cases have been transferred to other wards on account of surgical needs, or as showing no evidence of phthisis; seventy-six patients, who when admitted, were in an advanced stage of the disease, have died. There remain in the hospital 114 patients. Of these twenty are new cases not yet classified, forty are unable to leave their beds, and fifty-four are less advanced cases. Of these, twenty-five have shown decided improvement and show an average gain in weight of 6.75 pounds; thirteen show less improvement, but an average gain in weight of 1.9 pounds; sixteen have not improved, and show an average loss in weight of 1.31 pounds.

Association of American Physicians.—The seventeenth annual meeting of this society will be held at the New Willard Hotel, Washington, on April 29 and 30, under the presidency of Dr. J. C. Wilson of Philadelphia. The annual dinner will take place on Wednesday evening after the close of the meeting.

American Therapeutic Society.—The third annual meeting of this society will be held at the Academy of Medicine in this city on May 13, 14 and 15, under the presidency of Dr. R. W. Wilcox of New York. The secretary of the society is Dr. Noble P. Barnes of Washington; the chairman of the Committee of Arrangements is Dr. Thomas E. Satterthwaite of New York City.

The American Congress of Tuberculosis.—At this congress, to be held at the Hotel Majestic, New York, on May 14, 15 and 16, the following subjects will be submitted for general discussion: (1) Preventive Legislation, Embracing the Social, Municipal, and State Aspects of Tuberculosis. (What aid should be expected from the State in the cure and prevention of tuberculosis, and how shall this be secured); (2) Tuberculosis in its Pathological and Bacteriological Aspects; (3) The Medical and Surgical Aspects of Tuberculosis. (Embracing Sanitoria and Climatic Conditions, Light and Electricity; (4) The Veterinary Aspects of Tuberculosis.

An order has been issued by the War Department directing Major W. C. Gorgas, surgeon, U. S. Army, under whose administration, as sanitary officer, yellow fever has been eradicated from Havana, to remain in that city on special duty after the establishment of the Republic of Cuba and the evacuation of the island by United States troops. Major Gorgas will continue his investigations in regard to the relations between yellow fever and the stegomyia mosquito, and will no doubt assist the new-formed Havana Board of Health in an advisory capacity.

Pathological Society of Philadelphia.—At a stated meeting, held April 10, Dr. William Pepper presented a communication entitled "The Microscopy of the Blood Fifty Years Ago, with the Exhibition of a Specimen Mounted in 1852." He pointed out that even at that time much attention was directed to the study of the blood, and that leukemia had been described some six years previously. It was the general practice to make observations of the blood in the fresh state, and in the literature of the day Dr. Pepper could find no reference to a permanent preparation such as the one exhibited, and which was found among some possessions of his grandfather, Dr. William Pepper. The specimen was mounted on and viewed through a micro scope of contemporary form. Dr. M. Howard Fussell and J. Thompson Schell exhibited "A Large Ovarian Cyst," the part that was removed, together with its contents, weighing more than one hundred pounds. Dr. A. O. J. Kelly exhibited "An Enormous Vesical Calculus Successfully Removed by Suprapubic Cystotomy." The stone was ovoid in shape, light in color, as large as a good-sized fist or of two applied small-sized fists, and it weighed twenty-nine ounces. The operation had been performed within a week by Dr. J. B Deaver at the German Hospital and the condition of the patient was favorable. Dr. C. A. Herter of New York read by invitation a paper entitled "Experimental Glycosuria from Adrenalin Chlorid." He referred to observations made by others as to the development of glycosuria in lower animals from subcutanous and intravenous injections of preparations of adrenal gland and he detailed experimental observations of his own first with intraperitoneal injections of adrenal chloride, subsequently with local applications of this substance to the surface of the pancreas, and finally with applications of other reducing substances to the surface of the pancreas, all of which were attended with glycosuria, although such a result failed to follow the administration of adrenal chlorid by the mouth and the application of other substances to the gland, including those having oxidizing properties. Dr. A. C. Croftan referred to his own independent observations upon the development of glycosuria following the injection of adrenal extract, and to his view that the glycosuria was related, in part at least, to the presence of a ferment in the adrenal gland capable of converting the glycogen of the liver and the muscles into dextrose. Dr. Alfred Stengel reported some clinical observations in which intravenous injection of adrenalin chlorid in doses of two drams was followed by the appearance in the urine of a reducing substance not responding, however, to all of the tests for dextrose. In cases of typhoid fever in which adrenal gland had been administered by the mouth there was rise of blood-pressure of brief duration.

An Anglo-American Hospital at Cairo.—An Anglo-American Hospital is to be built at Cairo. The King and Queen of England have promised their patronage. Sir Edward Cassel will give $25,000 toward it, if the same sum is contributed from other sources.

Meeting of Legislative Committee of American Medical Association.—A conference was recently held in Washington of the legislative committee of the American Medical Association and the chairman of the legislative committees of a number of State medical societies, relative to National and State legislation affecting the interests of the medical profession. The chairman of the medical societies present represented the States of New Hampshire, North Carolina, Arkansas, New Jersey, New York, Massachusetts, Alabama, South Carolina, Minnesota, Michigan, Indiana, Pennsylvania, West Virginia, Maryland, Connecticut, Wisconsin, and several other states. A representative was also present from the Army, Navy, Marine Hospital Service, and Bureau of Animal Industry of the Department of Agriculture. The conference adopted committee reports which have for their object the securing of uniform legislation by the States and Territories which will permit a physician to practice in any state or territory, and the development of state medical organization to secure the enactment of legislation of importance to the profession. Dr. H. L. E. Johnson, chairman of the legislative committee of the American Public Health Association, made a report showing what had been accomplished in the way of National and State legislation. Surgeon-General Stern-being made a report relative to the proposed reorganization bill for the Army Medical Department and also referred to the work being done by the medical corps in the Philippines. The conference declared itself favorable, with some modifications, to the bills now pending in Congress to increase the powers of the Marine Hospital Service and to change its name to the United States Public Health Service. These bills had previously received the endorsement of the conference of State health officers which met in Washington some weeks before. Strong resolutions opposing the Gallinger antivivisection bill for the District of Columbia were adopted. Favorable action was taken on the Nelson bill to establish a department of commerce and labor, and on the Proctor bill for the payment of medical expenses incurred by officers and enlisted men while absent from duty by reason of sickness.

Pennsylvania Society for the Prevention of Tuberculosis.—At the annual meeting held April 9, Dr. Howard S. Anders was elected president in succession to Dr. Guy Hinsdale, who had held the office for three years and declined re-election. Drs. J. Solis-Cohen, Benjamin Lee, S. A. Knopf, Wm. Moss, Samuel G. Dixon, Lawrence F. Flick, Mr. Talcott Williams, Mrs. Wm. F. Jenks, Mr. Samuel Castner, and Miss F. W. Redfield were elected vice-presidents, Dr. A. H. Davisson, secretary, Miss E. W. Redfield, corresponding secretary, Mr. Jas. L. Stanton, solicitor, and the Commonwealth Title Insurance and Trust Co., treasurer.

Philadelphia Pediatric Society.—At a stated meeting held April 8, Dr. C. H. Weber exhibited "a case of aortic stenosis." The patient was a boy, about eleven years old, with recurrent symptoms of rheumatism, a positive agglutinating reaction with typhoid bacilli, but without other indication of typhoid fever, an enlarged area of cardiac dulness, a loud systolic murmur, and a marked systolic thrill in the aortic area. Dr. Robert G. LeConte read a paper entitled "Two Cases of Nephrectomy for Sarcoma of the Kidney in Childhood; Operative Recovery." In one of the cases marked improvement followed the operation, and life was prolonged for several months. The object of operation is either to save life when this is possible; otherwise to prolong life when recovery is not possible, or to relieve suffering and render death less painful. In some four cases out of seventy-five on record, life was prolonged for at least several years, and up to the time of report. Dr. M. H. Fussell reported "three cases of infantile scurvy." In all the condition closely simulated rheumatism, which is a rare affection in early childhood and infancy, and in none were the gums spongy or bleeding. In all, further, artificial food entered into the diet, and improvement speedily followed a change to milk-and-cream mixtures. Dr. Edwin Rosenthal read a paper entitled "Report of Six Cases of Surgical Erysipelas Treated with Antistreptococcic Serum without Benefit." The cases occurred in a limited epidemic, and recovery ensued in all, quinine and iron having been administered, and ichthyol having been applied topically after failure of the serum. Dr. Frederick Krauss read a paper entitled "Report of a Case of Cerebrospinal Meningitis probably due to the Pneumococcus, Followed by Recovery." The good result in this case was attributed to the heroic doses of alcohol that were employed. Dr. Alexander H. Davisson reported "a case of sclerema neonatorum."

Threatened Closure of the Hospitals in Queens.—The hospitals at Jamaica and Flushing, in Queens Borough will have to close within a few weeks, it is said, unless the city comes to their aid. They formerly received appropriations from the various villages in the county, but consolidation cut off this source of income, and they are now dependent wholly upon money raised by private subscription and the proceeds of entertainments, and receive for city patients less than it costs to maintain them. St. John's Hospital, in Long Island City, is the only one that benefits by an appropriation in accordance with its needs.

Destruction of Rats in Manila.—Dr. J. M. Maus, U. S. A., Commissioner of Public Health in Manila, has reported to the Philippine Commission that between September, 1901, and February, 1902, 33,772 rats were caught by the official rat catchers and natives. Of this number 32,756 were examined for infection at the health board's laboratory. Two hundred and twenty-nine bubonic plague rats were found, or seven tenths of 1 per cent. of the number examined. In January 16,776 rats were examined, and of these fifty-one were found to be infected, three tenths of 1 per cent. for the month, leading to the belief that the disease among rats is gradually disappearing. No plague cases were reported in January, 1902. The last case was reported December 24, 1901. In 1900 the disease was most prevalent in March, when sixty-four cases occurred, while in 1901 the climax was reached in May, with 124 cases. Every house in which infected rats were found was remodelled, cleaned and disinfected.

The Late Prof. Paul F. Munde.—At a recent meeting of the Medical Board of Mount Sinai Hospital, the undersigned having been appointed a Committee to draft resolutions on the death of Dr. Paul F. Mundé, reports as follows:

Whereas, Dr. Paul Fortunatus Mundé, after a faithful service of nineteen years at Mount Sinai Hospital, has been removed by an untimely death; and

Whereas, his Colleagues of the Medical Board had special opportunity during all these years to recognize in him the skilful physician, and to esteem him as a devoted friend,

Therefore be it Resolved, That the Medical Board of Mount Sinai Hospital place upon its minutes this record to show its appreciation of the great loss which the hospital has sustained; that it extend its sympathy to his family in their great sorrow, and that a copy of these resolutions be sent to them and be published in the medical press of the city.

(Signed) ALFRED MEYER, M.D.,
HENRY KOPLIK, M.D.,
HOWARD LILIENTHAL, M.D.

Fatal Blood Poisoning the Result of an Operation.—On April 6 Dr. W. D. Middleton, chief surgeon to the Chicago, Rock Island and Pacific Railway, and dean of the medical department of the State University of Iowa, died at Davenport, Ia., of blood poisoning, subsequent to an operation performed by him for appendicitis. The patient was in a gangrenous condition, and both Dr. Middleton and Dr. Braunlich, his assistant, were accidentally poisoned, and by late reports, the latter was said to be critically ill.

Cancer Research in Great Britain.—The British Cancer Research Fund has received three munificent donations of $25,000 each, one of which is anonymous, one comes from Mr. H. L. Bischoffheim, who for years maintained the Street Ambulance Organization of London, and the third is given by the Goldsmiths Company as a special memorial of the Coronation. This donation is accompanied by a stipulation that it shall be under the control of the Colleges of Physicians and Surgeons.—*The Hospital.*

International Conference on Syphilis.—The second International Conference on the Means of Prophylaxis against Syphilis and Venereal Diseases will be held under the patronage of the Belgian Government at Brussels from September 15 to 20. Governments and municipalities will be asked to send delegates, and invitations will be sent to members of the medical and legal professions, public officials, and sociologists who have given special attention to questions of hygiene and administration relating to prostitution and venereal diseases. The Permanent Committee consists of M.M. Jules le Jeune, Minister of State; Emile Beco, Secretary-General of the Public Health Service; and Dr. Dubois-Havenith, member of the Superior Council of Public Hygiene. All communications should be addressed to Dr. Dubois-Havenith, 19 Ru de Gouvernment Provisoire, Brussels.

Cancer in Germany.—Dr. Wutzdorff, one of the heads of department in the German Imperial Board of Health, has just published a paper containing important statistics with regard to the prevalence of cancer in Germany. His figures deal with (*a*) the statistics of public and private hospitals, and (*b*) with the statistics of the causes of death. The first part cannot, of course, be pronounced completely conclusive, since a large percentage of cancer cases are not brought into hospital at all. Still these figures, though incomplete, are most striking. It appears that in the year 1879 the number of cancer cases in German hospitals was 6,630 (2,732 male and 3,898 female), whilst in the year 1898 the number had increased to 24,166 (10,100 male and 14,166 female), that is an increase of 266 per cent. And since the total number of hospital patients had doubled in the twenty years, the real meaning of these figures is, that —as compared with other diseases—there were more than twice as many cancer cases in 1898 than in 1879. The "cause of death" list shows the increase of cancer from 1892 to 1898. In 1892 2.6 per cent. deaths were accounted for by 'new growth," and in 1898, 3.5 deaths per cent. of 100,000 inhabitants; 49.6 died of carcinoma in 1892, 70.6 in 1898—an increase of 18.5 per cent. in six years.

Effects of Cholera Inoculations.—Some interesting observations have been made by Major Buchanan and Captain Lamb on the effects of cholera inoculations, which may be thus summarized: (1) A preliminary infection of a dead vaccine a few days before the living material is inoculated has the effect of increasing the subsequent constitutional disturbance; (2) A slight increase in the amount of living material greatly increases the constitutional disturbance; and (3) A previous attack of cholera—within one month—decidedly lessens the reaction of a living inoculation. The chief inoculations for cholera are now at Goalundo, where the coolies for the tea gardens pass through, but the returns for cholera are optional with the employers, so that the information available is scanty.—*British Medical Journal.*

Obituary Notes.—Dr. Meredith Clymer died on April 20, at his home in this city, at the age of eighty-six years. He was born in Philadelphia and was a grandson of George Clymer, one of the signers of the Declaration of Independence. He was educated at the University of Pennsylvania, obtaining his medical degree there in 1837. He studied in Dublin, London and Paris, and then took up practice in Philadelphia, where he remained ten years. In 1851 he removed to New York and was appointed Professor of the Practice of Medicine at the University Medical College. During the Civil War he was a surgeon in the United States Volunteers, and Medical Director of the Department of the South. In 1871 he was made Professor of Mental and Nervous Diseases in Albany Medical College. He was a member of many medical and scientific societies and one of the five honorary members of the Association of American Physicians. He was a frequent contributor to medical journals, and acted as editor of the *Journal of Nervous and Mental Diseases* for several years.

Dr. Julius Wise died in Chicago on April 19, after a short illness, at the age of fifty-three years. He was a graduate of the Medical Department of the University of Michigan, in the class of 1872. He first practised in Memphis, where he was one of the most active workers during the yellow fever epidemic of 1878-79, and where he was Professor of Materia Medica and Therapeutics at the Memphis Medical College. Later he removed to Chicago. Although a practising physician, he was best known as a writer for the Jewish press, especially the *American Israelite.*

Dr. Nathaniel Marston Freeman of this city died suddenly on April 18, at the age of eighty-one years. He had practised medicine here for more than forty years, but retired several years ago.

The late Dr. Ervin A. Tucker. The Medical Association of the Greater City of New York has learned, with the deepest regret, of its loss by death of one of its most promising members, Dr. Ervin A. Tucker, one of the founders of the association.

By inherent ability, thorough preparation and hard work, Dr. Tucker had gained the front rank in his specialty of obstetrics, and had won the admiration and respect of his colleagues and his many friends. He seemed to be at the threshold of a most useful and distinguished career when his life closed. Be it hereby

Resolved, That we extend our deepest sympathy to the bereaved widow; that this note be entered upon our minutes, and that a copy be forwarded to the widow.

Edwin B. Cragin,
J. Clifton Edgar,
J. Milton Mabbott,
Committee.

The Cigarette.—Apropos of the tobacco war which is now raging in Great Britain, the *Lancet* once more takes up the subject of the harmfulness of the cigarette compared with other forms of smoking. The journal in question says:

"The cigarette is practically in direct contact with the air from the lighted end to the mouthpiece. Thus the smoke is invariably pulled while the products of combustion are complete. The pipe, on the other hand, is more like a retort in which destructive distillation and the formation of acrid oils are set up. One strong objection to the cigarette is that combustion is close to the nose and mouth. Thus air containing smoke from the lighted end, which is infinitely more pungent than the smoke drawn through the cigarette, is constantly inhaled. Much of the mischief from cigarette smoking arises from this fact. If smoke from the burning tip of the cigarette is purposely inhaled for a time, a sense of stupor sets in, while smoke drawn through the cigarette may be breathed the same way with comparative impunity. The same result is obtained with a cigar, but in a more emphatic manner. The use of the cigarette or cigar-holder is, therefore, calculated to obviate this source of mischief.

Correspondence.

OUR LONDON LETTER.

(From our own Correspondent.)

[illegible] DEBATE ON CANCER [illegible] — [illegible] — THE LATE DR. EDWARD LONG FOX.

London, April 4, 1902.

Dr. [illegible] delivered the Milroy lectures this year. [illegible] for the subject is [illegible]. [illegible] he had had many opportunities [illegible] and [illegible]. Of course, he has [illegible] been exposed to the infection, but he has escaped, and he attributes his immunity to an attack of what was called "house fever" when he was a boy. He first made a [illegible] on the "Alleged [illegible] of the [illegible] Fever," read in 1872 before the Epidemiological Society. He prefers the term typhus—the name used by his teacher, William Jenner, and which [illegible] [illegible]. It is [illegible] better than [illegible], which has been so freely used by the Army Medical Department, for we [illegible] of other general diseases by names denoting the organs in which their special lesions occur. It was only towards the middle of last century that the disease was differentiated from typhus, and typhoid [illegible] involves [illegible]. Dr. [illegible], like all Jenner's pupils, has the most profound veneration for his teacher's [illegible], and seems unable to resist the glamour of his great personality. [illegible] at times to give them [illegible] than [illegible] of credit. Dr. [illegible] evidently [illegible] to be just to all and gives a number of authors who had helped to elucidate the matter. Of English [illegible] Jenner, H. C. Barlow and A. P. Stewart. Possibly the latter it may be said that he certainly nearly reached the goal when William Jenner began his work. He had the enormous advantage of serving as a resident medical officer of the London Fever Hospital when he began his investigations, and he used his opportunity with rare diligence and [illegible], and so he was able to prove what others had asserted with more or less confidence—that typhus and typhoid are distinct diseases.

Dr. [illegible] has disinterred from the library of the Royal Medical and Chirurgical Society a Latin volume by Dr. Christopher Mayer, published at Vienna in 1[illegible]6. As there is no other known copy in our other medical libraries, your bibliographical enthusiasts may like to hear of so rare a work on fevers. It is entitled "Specimen Practicum de Remediis Efficacissimis in Morbis Contagiosis et Pestilentialibus Adnexa Commentatione de Contagio in Febribus Typhodis." Perhaps some of your librarians may find a copy.

The third evening of the debate on cancer at the Chelsea Clinical Society sustained the interest raised by the two others. Mr. D'Arcy Power, though a surgeon, devoted himself at one time to microscopic appearances, but with no better result than others, so now, he said, he had been seeking for an intermediate host. Influenced by the spread of typhoid in South Africa, it occurred to him that flies might carry cancer, and he had had three patients with [illegible], who attributed their malady to fly bites. He had asked Mr. Lowne about the house fly, who told him there were two sorts—the common, which had harmless mouth parts, and the stomoxys, which was armed with a set of lancets. The common house fly was the larger and when at rest held its head downward. The stomoxys held its head erect, and had three interrupted [illegible] spots on its back. He asked those interested to inquire if their patients had any recollection of being bitten, and if those who had the opportunity would send him specimens of stomoxys.

Drs. Gaylord and [illegible] sent a note on cancer in swine from the [illegible] State cancer laboratory and some microscopical [illegible]. You will probably know all about their researches, so I will only remark that they seem to think cancer in swine more frequent than we had supposed.

Dr. [illegible] referred to the increased consumption of meat, [illegible] that cancer was really a [illegible] of over-[illegible] which might [illegible] over-[illegible] cells [illegible]. Statistics of [illegible] were unfavorable to the salt hypothesis. The parasitic view he thought also unproved, though all would welcome it if [illegible] in regard to a remedy.

Mr. Eve said the cell was the [illegible] of malignant disease, and hope rested in [illegible]. When a serum or [illegible] toxin could be found which would kill spermatozoa and arrest the [illegible] of [illegible] epithelium, we should be nearer a destroyer of cancer cells.

Professor Adami of Montreal sent an interesting communication, in which he pointed out the want of proof of the existence of those specific [illegible] parasites which we have heard suggested. The prevalent conception of parasites within the cells he said [illegible] the idea of [illegible]; [illegible] the study of [illegible] the tumor cells [illegible] therefore [illegible] parasitic to the organism. Long continued action might, perhaps, like other irritants initiate abnormal and [illegible] growth, but he said that they seemed to be [illegible] a [illegible] of things.

Dr. Payne stated the hypothesis of his contribution—that primary cancer represented either [illegible] lesion on the surface, internal or external, where the germ entered the body, or an [illegible] of [illegible], which helped the germ [illegible] path. The latter was what produced the [illegible] tumors in the female [illegible].

On the [illegible] inst. there was a discussion at the Medical Society on the "Treatment of Puerperal Eclampsia." Dr. Herman opened by directly contradicting the teaching of the text-books that emptying the uterus stopped the fits and therefore that [illegible] should be the first thing in treatment. He pointed out that the most recent advocates of the procedure admitted that proof of its effect was defective, although it had been the positive [illegible] of at least three generations. He gave statistics from a number of lying-in hospitals to shew that the fits continued after delivery almost as often as they ceased. In [illegible] the reverse was the case in some hospitals. In recent times the mortality was about the same whether the uterus was emptied or not. As a prophylactic, he believed in inducing premature labor when there was much albumen in the urine. He had a good word for [illegible] during fits, and said, if delivery was undertaken in presence of convulsions, Cæsarian section was the best method. Dr. Herman further advocated the tepid bath as the most hopeful treatment in those cases of eclampsia in which death occurred through steadily rising of temperature and pulse. He related such a case which recovered under bath treatment after a temperature of [illegible]° and a pulse of 17[illegible].

Some differences of opinion were expressed, as might be expected, but Dr. Herman was not without supporters. Dr. A. Routh said the toxic condition of the blood, generally admitted, was relieved when the child and placenta were extruded. The tepid bath [illegible] failed; in one case it brought the temperature down from 107° to 101° several times, but the patient died.

Dr. McLean said the fits often diminished considerably after delivery, though they might not cease altogether. He mentioned that some early writer disapproved of rapid delivery.

Dr. Gow thought the process of inducing labor aggravated the fits, though they were relieved after the uterus was emptied. He thought morphine or chloroform better than more violent methods.

Dr. Gibbons said the poison could produce rapid degeneration of the vessels of the liver and other large glands, and the patient might succumb to the intensity of the poison. To dilute it he advocated saline injections. As a preventive, the urine of a pregnant woman should be more often examined, and if a large amount of albumen occurred, premature labor should be induced, though the patient appeared in good health.

Dr. Blacker would eliminate all the poison he could by v.s., even to 500 c.c. at a time, and dilute the remainder by salines up to about 1,000 c.c.

Dr. Handfield-Jones agreed, generally, with Dr. Herman, but he would not exclude operation in some cases even in the presence of fits.

The work of Dr. Monckton Copeman was made the subject of a question in the House of Commons. This was, apparently, at the instigation of the fanatics, and, of course, was misleading. The reply given on behalf of the Government was almost as misleading. The consequence is that not a few people, led by the faddist press, believe that [illegible] experimentation has been carried out on children—an absurd notion. If the officials who prepare answers for the Government on such questions cannot comprehend them and frame correct replies, their places should be taken by those who can.

Bristol is mourning the loss of a most distinguished and venerated citizen—Dr. Edward Long Fox, consulting physician to the Infirmary after twenty years' service on the active staff. He was an Oxford graduate and, in due time, an associated examiner at his alma mater. He was president of the British Medical Association when it met at Bristol in 1894, and always took a lively interest in its work—in fact, it is said he was one of the few who saved it from bankruptcy when at its lowest ebb. But medical affairs could not occupy all his attention. Every good and noble work had his sympathy and help. He was a fine specimen of a genial, courteous gentleman, a kindly medical adviser and consistent Christian. His chief works, "The Influence of the Sympathetic in Disease" and the "Pathological Anatomy of the Nervous Centers," must be well known to you. He died on Good Friday, aged seventy years.

NURSING IN PRIVATE INSANE ASYLUMS.

To the Editor of the Medical Record:

Sir: The first steps toward the correction of any abuse or evil are publicity of the facts and the awakening of public interest; after this the pressure of public opinion is sufficient to bring about a reform.

I desire to call the attention of the medical public, through your columns, to an abuse which should surely be remedied. I refer to the lack of proper nursing and care of patients in private lunatic asylums in the vicinity. First, as to the facts:

Case I.—A lady of wealth and refinement, who became insane in Germany, was brought home by her family, attended by skilled nurses, and, for a time, was kept in her home. She was then sent to Asylum A, where she remained for three years. During this time her nurses and companions were women obtained from the Young Women's Christian Association of this city at a cost of $20 per month—decent persons, but wholly untrained in the care of lunatics, and incapable of giving that mental direction and help which a good trained nurse can give. Subsequently, on her removal to her home and on being put in charge of two skilful nurses, a marked improvement occurred up to the time of her death, which took place from an intercurrent disease. She was charged $100 per week at the asylum, though the food was that of a $10 boarding-house.

Case II.—A young lady, who became acutely maniacal, was sent to Asylum B for care. Her nurses were dismissed and she was placed in charge of an Irish servant and a young French woman, who had failed as a teacher, and was willing to take a place as nurse. Neither of them had experience, and the days were passed in constant struggles between them and the patient. For months this condition went on, though the family were anxious to have extra nurses and were ready to pay for them. They were charged $75 per week. The patient had to be fed on milk and eggs only.

Case III.—A lady, suffering from chronic mania, has been ten years in one institution, Asylum C. She is happy and able to be diverted By accident I discovered that she was regularly locked into her room by her companion at 8 p.m., the door into this companion's room being thus closed till 8 a.m., while she was often absent. Considerable extra expense to the family was incurred, because the attendant had a large adjacent communicating room.

Case IV.—A lady suffering from melancholia had been well cared for by two trained nurses, and was improving when it was thought best to send her to Asylum D. On her admission her nurses were discharged, as the physician "preferred his own nurses." Two weeks later I found her locked in a room with a good-natured, ignorant Irish girl, who informed me that she had come to the asylum within a week and had never done any nursing before. As proper companionship is essential to recovery in melancholia, I remonstrated with the physician, but, no attention being paid to the protest, I removed her, and at home, under proper care, she recovered.

Case V.—A gentleman of means and high mental ability, who had an attack of mild melancholia, was sent to Asylum E. He had had a most faithful male nurse, intelligent, sober, and capable of managing him perfectly. Three days after his admission to the asylum, this man was unexpectedly discharged at night, and the patient was put in the care of a rough, dirty Swede, who had been hired that very day, and had never before acted as a nurse in an asylum. To my protest, the physician replied that he "could trust only his own trained nurses—others were liable to drink and disobey orders." Two weeks later my patient was found completely terrorized by this man, and complained bitterly of his treatment and lack of companionship. He saw the doctor for fifteen minutes daily, but was with the attendant all the time. The man's habits were filthy, and he was better fitted for a stableman than for a nurse. The patient offered to pay for the services of his former nurse, and to pay his board in addition to the $50 per week which he paid for his single room. This proposition was declined. Hence, I removed him to another institution, where he is being properly nursed, and *is recovering* rapidly.

Here are five cases in five different private asylums near New York, all of which have a good reputation. In all the same abuse exists—unintelligent care is the rule. In all these places the doctor in charge sees the patient once a day or every other day, as all have offices in New York. In all the food is plain but wholesome, and served unattractively and, usually, cold. In all prices from $50 to $100 a week are charged. Double the charge would have been cheerfully paid for skilful attendants in every case mentioned.

Secondly, as to the remedy:

It is well known that at Bloomingdale Asylum there is a good training school for nurses, from which graduates come out every year competent to take care of cases of mental disease. If it became imperative upon these asylum physicians to employ trained nurses of good capacity, they could be found and supplied. But since there is no demand made, excepting by patients whose statements are not accepted, or by relatives whose protests are disregarded, the present evils continue. Many physicians wash their hands of a patient as soon as he is consigned to an asylum, and if they do visit him, it is soon made clear that such visits are regarded as an interference by the doctor in charge. It seems evident, therefore, that public opinion should be aroused in this matter, and I hope this statement of facts *of my personal knowledge* may awaken such a demand for the reform of these abuses that good may come of this protest against an existing condition.

Yours respectfully,
M. Allen Starr, M.D.

ON THE TRANSMISSION OF YELLOW FEVER BY VESSELS.

SECOND COMMUNICATION—A REPLY TO DR. DOTY.

By EDMOND SOUCHON, M.D.,
NEW ORLEANS, LA.
PRESIDENT OF THE LOUISIANA STATE BOARD OF HEALTH.

To the Editor of the Medical Record:

Sir: Dr. A. H. Doty, Quarantine Officer of the Port of New York, published in the Medical Record of March 8, 1902, a paper entitled, "Regarding the Infectious Agent of Yellow Fever; a reply to Dr. Souchon."

Dr. Doty says that: "It can hardly be said that Dr. Souchon's communication, which appeared in the Medical Record of December 28, has in any way damaged the argument already claimed that yellow fever is not transmitted by personal contagion or by clothing, bedding, etc., nor has it proven that the mosquito is not the medium of infection of the disease."

But these are not the points at issue.

In our paper of December 28, 1901, on the "Transmission of Yellow Fever by Vessels," we took exception to Dr. Doty's statement that: "In accordance with the above views, the treatment of incoming vessels from ports infected with yellow fever becomes very simple: *if they are five days or more in transit*, and all on board are found to be well after a careful inspection and the use of the clinical thermometer, the vessel, its passengers, and crew shall be released without further detention or treatment.

"If the vessel has been less than five days in transit, all on board who cannot present satisfactory evidence of immunity should be removed and held for observation until the completion of a period of five days from the time of departure from the infected port, and then released only after a careful inspection. When yellow fever is found on incoming vessels the procedure should differ only so far as it concerns the removal of the patient to a properly constructed hospital or apartment for treatment."

Of course, we have read Dr. Doty's paper most carefully, and yet we fail to see in it a reply to the exception we took to his statement.

We contended that the practice recommended by Dr. Doty was unsafe, and we cited a number of cases of vessels in which yellow fever developed on the vessel after it had been more than five days out.

We fail to see that Dr. Doty has proven that these vessels treated as he recommended would be safe.

Dr. H. R. Carter in a recent paper in the Medical Record of March 22, 1902, adds to our list the following vessels as having developed yellow fever after having been more than five days out:

1888, *The Riagino*	11 days out.
1890, *The Avon*	38 days out.
1890, *The Castilla*	12 days out.
1890, *The Gran Canaries*	7 days out.
1891, *The Gustave & Oscar*	7 days out.
1891, *The Emily Postel*	16 days out.

The explanation of Dr. Doty that the first patient on the Bark *Excelsior* contracted the yellow fever in New Orleans falls to the ground when it is known that there was only one case of yellow fever reported in New Orleans that year, as proven by the rigorous investigations made by all the health authorities, specially those of Texas and of the National Board of Health, a graphic account of which can be read in the Report of the Louisiana State Board of Health, 1880-81, Vol. III., pp. 68 and following.

The development of yellow fever after disinfection does [illegible] that the [illegible] process has been imperfectly done. [illegible] to the fact that during the [illegible] up of [illegible] necessitated by the [illegible] some [illegible] focus of infection has been set free and has affected some other [illegible].

We [illegible] quite thorough [illegible] to do so in the light of [illegible] practical facts regardless of the cause, [illegible] or [illegible].

New Orleans, La.

SPECIFICS AND DISINFECTANTS.

To the Editor of the Medical Record.

Sir: In the Medical Record, March 1[illegible], 1902, is published an article by Andrew H. Smith on "Specific Medication." On page 4[illegible] he says: "Not one of the recognized specifics would be employed outside of the body for its disinfectant properties." Of course, the statement is unintentional, as it only needs to be indicated to be corrected, but the correction should be made. Iodine, the active component of iodide of potash, was recommended by Joseph Jones as an application in post-mortem and dissection wounds. Lately Carl Beck has advised its use in certain recent infections. Bichloride of mercury needs only to be mentioned. Both are recognized specifics in syphilis.

C. S. Bird, M.D.

Tampa, Fla.

Book Reviews.

Topographical Atlas of the Spinal Cord, by Alexander Bruce, A.M., M.D., F.R.C.P.E., F.R.S.E. London: Williams & Norgate, 1901.

Dr. Bruce's valuable and original work is in the form of a quarto, containing thirty-two photogravure plates, with over sixty different figures illustrating the accompanying text. The object of the author is to show the arrangement of the groups of cells at the different levels of the spinal cord. Some contributions to cell-grouping have been made by previous investigators, but no one before has done it so completely, systematically, and objectively. The ordinary plates illustrating these different groups have been copied from text-book to text-book without much, if any, change. A comparison of the cell groups shown here with those shown in Quain's "Anatomy," for example, shows that some changes and rearrangements were necessary.

The author has made sections through each segment of the spinal cord, and, having stained these, has made photographs with low and high magnifying power. Reproductions of these photographs are given on each plate, so that one sees first the general arrangement of the cells and of the gray and white matter, and then, under higher magnifying power, the exact grouping in the anterior horns.

Dr. Bruce's work is always of the most careful and trustworthy character, and the present book is one which will have permanent value in anatomical science, and should add greatly to the reputation of the author.

Photographic Atlas of Diseases of the Skin. By George Henry Fox, A.M., M.D. Parts V and VI.

The illustrations in the fasciculi before us include sycosis, scrofuloderma, syphiloderma, papulo-squamosum, eczema papulosum, morphœa, pityriasis seborrhoica, chromophytosis guttata, psoriasis gyrata, pityriasis diffusa, and fibroma. Both morphœa and fibroma have two figures on the plate. The names "pityriasis seborrhoica" and "pityriasis diffusa" might be questioned by some as applied to the cases depicted. Both might, with equal propriety, it would seem, have been termed eczema seborrhoicum. The text, however, explains the matter. The plates are excellent, and the color reproduction is far superior to that of some colored plates brought out in recent years. The text is carefully prepared, and goes into treatment with formulæ and details.

The author and publishers are between them making a very attractive work.

The Pathology and Treatment of Sexual Impotence. By Victor G. Vecki, M.D. Third edition, revised and enlarged. Philadelphia and London: W. B. Saunders & Co., 1901.

This work is characterized by a strong personal element. While the author has quoted freely the views of others, his own firm opinions are put forward with the strength of conviction, and while one cannot always agree with his deductions, one must respect his honesty of intention. In the preface to the third edition, a critic of the first, whose "assault" is deemed harsh, is classed among those who have misunderstood the book altogether. We find nothing in the work which a physician should not read; but it is the class of work which undoubtedly obtains a large lay audience, no matter what the intention may be, and here would be the danger of any misunderstanding. Its popularity is proven by its circulation making necessary a new edition at this time.

Transactions of the American Otological Society, Thirty-fourth Annual Meeting, held at New London, Conn., July, 1901. Vol. VII, part IV, published by the Society, 1901.

This pamphlet, covering pp. 475-589 of the current volume, is edited by the Secretary of the Society, Dr. F. L. Jack of Boston, who has excellently performed his task. It contains an appreciative obituary notice of the late Dr. H. D. Noyes, written by Dr. Gruening, eight papers on otological topics, and a complete bibliography of otological literature for the year ending June 1, 1901, compiled by Dr. H. A. Alderton of Brooklyn.

Guide de l'Examen Gynécologique. Par L. Léon Archambault. Paris: A. Maloine, 1901.

This convenient little book of 116 pages is, as its title indicates, not a treatise on gynecological examination, but merely a guide to the same. It is profusely illustrated. The writer has previously paid special attention to the difficulties incident to gynecological examination, and has embodied his experience in the present volume.

A Textbook of Medicine for Students and Practitioners. By Dr. Adolf Strümpell, Professor and Director of the Medical Clinique at the University of Erlangen. Third American edition, translated by permission from the Thirteenth German edition by Herman F. Vickery, A.B., M.D., Instructor in Clinical Medicine, Harvard University, etc. With Editorial Notes by Frederick C. Shattuck, A.M., M.D., Jackson Professor of Clinical Medicine, Harvard University, etc. With one hundred and eighty-five illustrations in the text and one plate. New York: D. Appleton & Co., 1901. 1,242 pp.

A new translation of this much used textbook cannot fail to attract the interest of a large number of English-reading students and practitioners, especially when it is remembered that seven new editions have appeared in Germany since the last American issue. In consequence of these many revisions, the work has been practically rewritten, but still retains all the vigor, balance, and hard sense of its predecessors. We notice particularly a complete change in the chapters on diseases of the stomach, which have been brought thoroughly up to date, and the author gives us therein one of the best expositions on the subject that has appeared in a general textbook.

The translators have added such information as seemed to be useful to American readers, the whole chapters on the plague and on yellow fever, together with numerous annotations, being inserted in brackets when by the editor, and signed if the translators are responsible.

Physicians' Account Book. By J. J. Taylor, M.D. Philadelphia: The Medical Council, 1901.

The special feature of this book is that it combines in one volume both daybook and ledger. It is portable, and arranged so that any account appearing therein will stand every legal test in case of dispute. Its simplicity, completeness, and economical price cannot fail to make it extremely popular with the active practitioner.

The Standard Medical Directory of North America, Consisting of Twelve Departments, including Directory of Physicians of North America, Medical Colleges, Medical Service of the United States, Medical Societies, Medical Practice Acts, Medical Publications (including Books and Periodicals), Mineral Springs, Drugs and Medicines, Medical and Surgical Products, Manufacturers and Life Insurance Companies. Handsomely bound in red buckram, 824 pages, imperial octavo. Price, $10.00. Chicago: G. P. Engelhard & Co., 1902.

This new directory has a very attractive appearance with its clear type, convenient arrangement of matter, and clear red binding. Being the latest, it naturally aims to be the best of the general medical directories, but we cannot say that it has succeeded in its first edition. We recognize, of course, the immense difficulties of preparing an accurate list of over 100,000 names, and an occasional inaccuracy should not be too harshly commented upon. The reviewer can only tell of his own test of the work. When the book came to his notice he happened to want the address of a prominent surgeon in a Pennsylvania city, but on turning to that city could not find the name. This shook his confidence in the book, and he then looked for his own name; that, too, was not to be found. His confidence was now still further shaken, and he turned to the name of a friend; this name he found, indeed, twice on the same page, once under the man's first name, the second time under his middle name. It is only fair to add, however, that he then looked up twenty names of men in different parts of the country and found them all. There is one omission in the book that detracts considerably from its value as an aid in finding people, and that is an alphabetical list of all the physicians now grouped under states and towns. A man's town is often unknown, as well as his street address, and the function of a work of this kind is to supply just such information. We doubt not that subsequent editions of the directory will be improvements on the present in the way of accuracy and completeness, but even this one, for a first attempt, is not so bad.

THE PRACTICAL MEDICINE SERIES OF YEAR BOOKS. Comprising ten volumes on the year's progress in medicine and surgery. Issued monthly. Under the general editorial charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Vol. II. GENERAL SURGERY: Edited by JOHN B. MURPHY, M.D., Professor of Surgery, Northwestern University Medical School. Chicago: The Year Book Publishers, November, 1901.

THE vast amount of new knowledge which is being offered the profession in journals from all parts of the globe has necessitated the modern scheme of condensation in book form of this material, which for the busy practitioner would otherwise remain inaccessible, except, perhaps, in but small proportion. In the present issue, under the able editorship of Dr. Murphy, we have a particularly valuable digest of the year's advances in surgical diagnosis, pathology and treatment. He has selected what would be practical and useful for the many who are general surgeons rather than for those who are doing special work.

The book is divided in accordance with the different regions, and deals only with the recent articles, presupposing, quite properly, a knowledge of fundamental principles and ordinary procedures. He has edited the work of others as it has appeared without changing the conclusions or intent of the articles, except to condense. He has however, added a few editorial comments at the end of several sections when he wishes to emphasize special points, rather than with the purpose of criticism.

NOTHNAGEL'S ENCYCLOPEDIA OF PRACTICAL MEDICINE, VARIOLA, VACCINATION, VARICELLA, CHOLERA, ERYSIPELAS, WHOOPING COUGH, AND HAY FEVER. By H. IMMERMANN, TH. VON JURGENSEN, C. LIEBERMEISTER, H. LENHARTZ, G. STICKER. Edited, with additions, by JOHN W. MOORE, M.D., F.R.C.P., Professor of the Practice of Medicine in the Royal College of Surgeons in Ireland. Authorized translation from the German, under the Editorial Supervision of ALFRED STENGEL, M.D., Professor of Clinical Medicine in the University of Pennsylvania. 682 pages. Philadelphia and London: W. B. Saunders & Co., 1902.

THE second volume of the American edition of Nothnagel's Encyclopedia gives a timely exposition of diseases which are of extreme interest and of widespread prevalence. Nearly a half of the volume is apportioned to the subjects of Variola and Vaccination, and the masterful discussion of the same merits the highest praise. The history is especially full, and is attractively told, while the scientific descriptions are exhaustive and convince the reader of the author's fairness and deep knowledge. To any doubter of the efficacy of vaccination, if he be open to argument, a perusal of this section would settle his opinion once and for all. To render the articles more complete, there have been included interesting chapters on the inoculation of human smallpox and on the pock diseases of animals.

Chickenpox is more concisely described, but is also excellent, and in it one can find all that is of ordinary interest in this quite benign and, therefore, less important disease.

Cholera Asiatica and Cholera Nostras occupy a full hundred pages and leave nothing to be desired. Especial interest will be attached to the methods of prophylaxis, and so successful are the means advised that to those engaged in quarantine work the reading will prove both interesting and an incentive to active precautionary methods, which, naturally, arises from the hope of a successful outcome of efforts to keep away this dread scourge.

To the surgeons the sections on Erysipelas and Erysipeloid will prove most acceptable. Thoroughness and graphic description characterize them both. Whooping-cough and Bostock's Summer Catarrh completes the volume, and are most excellent monographs, although adding but little to one's hope of combating these troubles in a way more successful than in the past. The excellence of the original has left little for the editor to add, but such that he has seen fit to incorporate shows good judgment, and will serve to make the book even more acceptable to the English reader.

Progress of Medical Science.

The Boston Medical and Surgical Journal, April 17, 1902.

Abdominal Hysterectomy for Uterine Cancer.—J. C. Irish holds that in cases of cancer involving the uterus alone, whether of the body or the cervix, abdominal hysterectomy is a very simple and attractive operation. It is attended with less than 5 per cent. fatality. The author protests against the pessimistic view so generally held that cancer of the cervix is an incurable disease. In the cases upon which he has operated he has had about 75 per cent. of permanent cures. These results, so exceptionally favorable when compared with operations for cancer in other parts of the body, are due to the anatomical relations of the uterus, and to the fact, except where the malignancy begins in an existing fibroid, that it attacks the endometrium which is isolated from everything else by the thick uterine muscle. The conclusion is that abdominal hysterectomy fulfils all operative requirements, and whatever advance is made in treatment must be in some direction outside of operative procedures.

The Nature of Cancer and Its Treatment.—In a paper on the "Treatment of Cases of Carcinoma Uteri not Justifiably Treated by Radical Operation," Albert H. Tuttle refers to a line of investigation which seems to him to open up the principal route for advancement in the treatment of this disease. He refers to hypodermic treatment with various chemicals, such as oils, alcohol, etc. His researches on *lunatia* embryos has inclined him toward the theory that cancer is the result of a change in the environments of a cell or group of cells by which their normal nutrition is affected and which results in their active proliferation, contrary to the natural laws of growth. By this abnormal multiplication they become a band of outlaws that war upon their neighbors, and finally end in the complete annihilation of the body. Once a cell or group of cells has broken loose from the laws that bind it to the animal whole, the progeny inherit the ban of the parent and continue to work out the war of destruction. This theory is borne out by the facts that the growth arises in certain organs at a time when their functional activity is diminishing or has already ceased. that it often starts at a joint subjected to continued irritation, and that hereditary influences play an important part in their causation. The method of treatment by hypodermic injections of antiseptic fluids is of possible value, and investigations and experiments along this line should be encouraged.

Journal of the American Medical Association, April 19, 1902.

The Diagnostic Value of Tuberculin.—C. M. Wood presents the following conclusions: Tuberculin, in doses of .005, carefully increased, when necessary, to .010, produced no bad effects in simple or complicated tuberculous or non-tuberculous cases. The characteristic tuberculin reaction is shown by a rise of at least two degrees in temperature, reaching its height in from six to thirty-six hours after the injection, typically at the eighteenth hour, and accompanied by at least two of the following symtoms: Chilliness, headache, nausea and muscular pains. The tuberculin test ranks in value with the Widal typhoid test, since in the former the technic is simpler; the materials are more readily obtainable and more permanent; the danger is no greater and the information obtained is scarcely less reliable.

The Paraffin Injection Treatment of Gersuny, with a Report of Cases.—R. M. Parker reviews the original experiments in this direction: He finds that most satisfactory results have followed the injections performed for the correction of unsightly deformities following cicatricial contractions resulting from wounds and loss of tissue through disease or operative measures, *e. g.* saddle-nose, etc. The paraffin employed should have a melting point slightly above the normal body temperature, *i. e.* between 99° and 104°F. If it is below the body norm, it will soon be carried away by the lymphatics, and if the paraffin is too hard it may cause necrosis. The preferable syringe to use is one made entirely of steel. The usual antiseptic precautions must be most scrupulously observed. A possible danger is that of lung embolism if the injection is made directly into a vein. The author thinks it justifiable to claim for the measure a permanent place in the treatment of appropriate cases.

The Etiology and Spread of Typhoid Fever.—According to Victor C. Vaughan, this disease is disseminated by man himself, through the air. through drinking water, is favored by certain conditions of the soil, is carried on the person or in clothing, and frequently by flies. Increased susceptibility arises from bodily fatigue and mental worry. The disease is more prevalent among the well-to-do than among those suffering from poverty. The belief that immunity to typhoid observed in advanced

[illegible] Medical Journal, April [illegible].

The Effect of Osteitis of the Knee on the Growth of the Limb.—From the study of a series of cases Henry Ling Taylor comes to the following conclusions: (1) Gonitis in childhood usually causes lengthening of the affected limb when approximately straight and this may persist for eight years or more. (2) This lengthening is mainly due to overgrowth of the femur, and may often be detected within six months of the onset. In adolescents and adults after cessation of active disease begun in childhood, the femur and limb may be considerably shortened. (3) The tibiæ are usually equal in length in the early stages, afterward the affected tibia may be slightly longer for a time, but is more often shorter even in the first two years; the shortening increases in the older cases and after subsidence of inflammation. (4) With limbs of equal length and a duration of disease of several years, the femur of the affected side will be found longer, the tibia shorter than its mate. (5) The feet and patellæ show a difference in favor of the sound side after a year's duration and often before. (6) Stimulation of growth at the lower end of the affected femur and more rarely and in less degree at the upper end of the tibia is usually accompanied by retarded growth in other parts of the limb; growth in the femur itself is finally retarded, and the final result, after many years, may be considerable shortening of the femur, tibia and limb.

Hæmaturia.—W. K. Otis reviews this subject in a general way, enumerating the tests for the detection of blood in the urine. Differential points are mentioned bearing on the question of the source of the blood. He divides the urinary tract into four portions: (1) From the external meatus to the compressor urethræ muscle, (2) The prostatic urethra, (3) The bladder, and (4) the kidneys, their pelves and ureters. Occasionally the hæmaturia will be intermittent. This is due to a temporary stoppage by a clot of the ureter on the affected side, so that all the urine secreted comes from the healthy kidney and is therefore clear, and this is almost pathognomonic of kidney hemorrhage. Sometimes, however, this condition is closely simulated when the lesion is in the bladder. When more blood is found in the morning, after rest, it indicates that the hemorrhage is, probably, of renal origin, for exercise increases vesical hemorrhage, but is, as a rule, without effect on that of renal origin. The cystoscope is frequently of great service in rendering a diagnosis possible in these obscure cases, and the presence of blood casts is pathognomonic. So also are the fibrin casts of the larger divisions of the kidney pelvis, so that all clots passed in the urine should be carefully floated out in water, in order to recognize, if possible, in what portion of the urinary tract they were formed. Long, round clots, resembling angle worms and about as thick as the ordinary lead pencil, are formed in the ureters, while frequently unmistakable casts of the pelvis or calices of the kidney will be passed, rendering the diagnosis absolute.

American Medicine, April 1[illegible], 1902.

Suggestions to Anæsthetizers.—George De Tarnowsky gives the following suggestions: Always reassure the patient before beginning an operation. Avoid or lessen the sense of suffocation by starting with a small amount of the anæsthetic, holding the cone six inches from the patient's face, and decreasing the distance by gradual degrees. Count out loud from 1 to 100, requesting pa-

[illegible]

Ocular Affections Associated with Glycosuria, with Especial Reference to Central Amblyopia.—Walter L. Pyle says that diabetes [illegible] or other disturbances of the carbohydrate metabolism may affect any part of the visual apparatus. The ocular changes may be produced [illegible] or through the associate general debility. The ocular affections may vary in severity from a slight defect of accommodation to a [illegible]. Minor visual disturbances are often made worse by fatigue or continued [illegible] and may increase [illegible]. The intraocular hemorrhages may be extensively developed, and there is [illegible] inflammation of the optic nerve. It is not common to find albuminuria coexistent with glycosuria, and the retinal changes may present a mixed picture, or a typical albuminuric retinitis may be present in a patient with diabetes. Central amblyopia may exist in glycosuria entirely independent of the toxic influence of alcohol and tobacco, or in patients addicted to the use of these substances they may be the prominent factor in causation. In chronic cases of glycosuria, with the exception of cataract, the ocular symptoms are often present when the constitutional and urinary symptoms are not marked. The ocular symptoms may be the first to lead the patient to seek medical advice. The prognostic significance of the ocular disturbances is not definitely established, on account of the great difference in pathogenesis, severity and ultimate issue of the numerous forms of glycosuria. Even in well-marked cases not only may formidable eye lesions improve, but the patient's general health may be restored. Again the ocular symptoms may remain stationary and the general health improve, or a case of diabetes may proceed rapidly to a fatal termination without showing marked ocular disturbances. Hemorrhagic retinitis and amaurosis preliminary to coma are the most serious symptoms. The ophthalmoscopic observation of greatest value in prognosis is the state of the retinal vessels, as this may be taken as an index of the patient's general vascular condition.

Medical News, April 1[illegible], 1902.

General Anæsthesia in the Plethoric.—M. L. Maduro advocates the following order in administering anæsthetics to plethoric subjects. Immediately after the nitrous oxide, give a few whiffs of ether, then give chloroform for an average of ten minutes, continuing with ether graded with a small amount of air for the rest of the operation. No harm can come from such frequent change of narcotics. Spasm of the respiratory muscles during ether narcosis in the plethoric suspends thoracic movement, and leads to an overdistended state of the right heart. Chloroform relieves that distension, induces deeper and quieter breathing and causes the pulse to become full and regular. This is only temporary, for chloroform given for any length of time will depress the heart, so ether given again will steady the pulse and cause the continuance of the quiet breathing. Gas is given at first because it is well tolerated and is safer and quicker. Pharyngeal stertor can be overcome by pulling the jaw forward. Some short-necked patients breathe more easily with the head slightly raised by a hard pillow, but the majority fare better with the head low and well extended. It is generally well to turn the plethoric patient's head to one side. The observation of these hints will usually do away with the dangers connected with administration of anæsthetics to the plethoric.

Clinical Expression of Chronic Myocarditis.—J. H. Musser declares that just as chronic myocarditis may exist without physical signs, so it may be devoid of clinical expression. Again the symptoms may persist for years and be most distressing and terrifying. The cardiac symptoms compel the patient to seek relief. Heart tire, as seen in cardiac debility, is out of proportion to the evidence of senile decay elsewhere. Weakness out of proportion to the seemingly strong appearance of the patient, is characteristic. Tachycardia is the rule and the pulse is small and feeble. If symptoms of dilatation of the heart arise it is unusual to have anginal symptoms.

A patient with myocarditis may have one attack of angina terminating in death without premonitions of cardiac disease. In these cases there is often found extensive coronary artery disease, death being due to thrombosis. Oftentimes the symptoms of angina are attributed to some gastric disorder. In one case noted, there was intense pain in the jaws. Allied to the anginal paroxysms is the curious localized substernal distress. It is a most difficult problem to distinguish the true and false forms of angina. Myocardial dyspnœa is frequent. A very rapid heart is often due to myocarditis. Usually there is some arrhythmia. Patients with the syndrome-bradycardia, syncope, convulsions, and pseudo-apoplexy, rarely suffer from angina or from severe arrhythmia. Myocarditis may have no other clinical expression than arrhythmia alone. Various combinations of the foregoing symptoms are often met with in cases of myocarditis.

Philadelphia Medical Journal, April 19, 1902.

Four Cases of Æstivo-Autumnal Malarial Infection at West Point., N. Y.—Thomas W. Jackson believes that there is a greater prevalence of the æstivo-autumnal parasite in this latitude than is generally supposed. This tropical parasite may have been introduced by soldiers returned from Cuba. This infection is very resistant to treatment, cases being on record in which the parasites have, undoubtedly, existed for more than two years, in spite of treatment. In one of the cases reported in this paper the affection had persisted for over two years. Only one of these four cases originated in Cuba. From his experience in cases of this nature, the writer thinks that the occurrence of crescents should not be depended upon, solely, for the diagnosis of this condition. The type of fever in his cases was very varied, and illustrates the irregularity of the manifestations of the malignant parasite. Correct diagnosis is necessary, as treatment appropriate in cases of ordinary benign malarial fever is inadequate in infections of the tropical parasite. Diagnosis should be based less on the temperature curve than upon the microscopical findings.

The Prevention of Neurasthenia after Surgical Operations.—Charles W. Burr states that neurasthenia may develop, or if previously present become more marked, after an operation of any kind, but is more frequently seen after surgical treatment of any of the chronic affections of the internal or external genitalia in women. Post-operative neurasthenia may occur as well in men as in women. True neurasthenia may follow acute surgical diseases. In the cases in which immediate operation is necessary, prevention of this condition is impossible. All that can be done is to make a careful study of the patient and institute those measures that are best suited to lead to speedy recovery. Certain chronic diseases are always accompanied by neurasthenia, for example, varicocele. In many cases of chronic surgical disease it is well to put the patient to bed for several weeks before operation. The diet should be regulated. If she is chronically starved, forced feeding is indicated. In certain cases milk alone is the best diet, but in a majority of cases a generous varied diet is preferable. Massage and faradic electricity should be used. Sometimes operation can be entirely avoided. In others the shock of operation will be less, and recovery quicker.

The Bacteriology of Erysipelas.—G. E. Pfahler describes the organism which he has found in the tissues of eighty-six different cases of erysipelas. The diagnosis in each case was confirmed by another physician. In nearly all of the cases some antiseptic application had been made previous to the bacteriological examination. This was done to eliminate foreign organisms from the surface of the skin. The writer describes this organism as follows: Spherical cocci, about the size of the pneumococcus, usually occurring in pairs, often singly, and very rarely a chain of four is seen, which is, probably, an accidental arrangement of two pairs. As observed in the contents of the pustules, in the blood of the inflamed part and in the blood from the rabbit, it has been seen only in pairs, and at times appears to be encapsulated. It is found both outside of and within the leucocytes. It is readily stained by aniline gentian-violet, by carbol-fuchsin, and by Gram's method. It does not stain well with Löffler's alkaline methylene blue, nor with Gabbett's methylene blue. The writer believes that this diplococcus is the most common cause of erysipelas, or of a disease which at present cannot be diagnosed from erysipelas. Koch's postulates have been demonstrated with reference to this organism.

The Lancet, April 5, 1902.

The Supposed Infectivity of Desquamation in Scarlet Fever.—C. K. Millard opposes the current opinion that scarlet fever is infectious during desquamation, advancing the following reasons for his views: (1) Careful evidence does not support the old theory; (2) Infectivity begins prior to the onset of desquamation and frequently continues long after the latter has ceased; (3) Scarlet fever wards, though abounding in desquamating epithelium, are not a danger to neighboring houses; (4) The fact that the proportion of "return cases" does not appear to be increased among patients sent out from the hospital still desquamating,.

The Topical Application of Mucin in Certain Affections of the Nose, Throat, and Ear.—W. Stuart-Low finds this remedy of value in pale and dry conditions of the mucosa of the upper air tract. Its action is soothing and emollient. It moistens the surface, softens incrustations, facilitates their removal and prevents their re-formation. The author dissolves a tablet containing five grains of mucin, five grains of bicarbonate of sodium, and one grain of menthol in one ounce of sterilized warm water and sterilized warm lime water, equal parts. The remedy is applied, in spray, twice daily. The spray must be a coarse one, and it is a good plan to drive clean warm water through it frequently to prevent clogging. The same tablet may be given internally before and after meals to relieve concomitant gastric irritation and constipation.

The Lancet, April 12, 1902.

A Case of Nutmeg Poisoning.—R. A. Pitter was called to a young woman, who was said to be in a "fit." He found her collapsed and with the odor of nutmeg on her breath. It was learned that she had taken, for the purpose of bringing on the menses, a whole nutmeg grated in a wine-glass of gin. The monthly flow had been delayed two weeks and the patient feared pregnancy. Her general condition began to improve in about an hour, and her stomach was thoroughly emptied. She remained in muttering delirium for one night, slept heavily the next day and awoke fully recovereed.

Abiotrophy.—By this term W. R. Gowers refers to degeneration or decay in consequence of a defect in vital endurance. Illustrations of this are seen in baldness and early grayness of the hair. The muscular system shows similar changes, which we include under the general name of muscular dystrophies. Here, the fiber after development ceases to maintain its full nutrition; it wastes and ultimately perishes, while the connective tissue between the fibers takes on an overgrowth. The nervous system pre-eminently shows these "abiotic" changes. They are seen in such conditions as anterior poliomyelitis, spastic paraplegia, the optic nerve degenerations, Friedrich's disease, etc. The general object of the paper, says the author, is to call attention to the two forms of death, somatic death against which we ever strive and which we endeavor to postpone as long as possible. The other aspect of death—the termination of life of isolated structures in the body—is to us what we call disease. It does not of necessity involve the termination of general life, but it is not less to be striven against, although the strife must often be in vain. The discernment of these diseases which we may call "abiotic," the recognition of the symptoms, the course, and the conditions which indicate them is of extreme importance. We must endeavor to check their progress, for we seldom know the strength or feebleness of the tendency, or whether it can be hindered, but the discernment of the nature of these maladies will often enable us better to perceive why treatment fails, and it may save from useless prolongation of attempts to perform the impossible.

On a Case of Pneumococcic Gastritis and General Infection.—The case is reported by A. G. R. Foulerton. His patient was a man of twenty-six years, who had had a quinsy two weeks before. Three days before admission to hospital he had begun to bleed from the nose, and the hemorrhage, though slight, had continued. He had vomited considerable foul, dark matter. He was intensely anæmic, and died in a condition of severe dyspnœa on the third day after admission. Autopsy showed the general condition of an infection, and bacteriological examination showed that this infection was due to the pneumococcus. A consideration of the pathology of the case suggests that the primary lesion was, perhaps, a pneumococcic infection of the right tonsil, though this was not proved. The infection of the stomach then resulted from the swallowing of the parasite, and the general infection followed the invasion of the stomach. The healthy stomach, with its strongly acid secretion, would in all probability be an extremely unfavorable site for the growth of diplococcus pneumoniæ, and it is not unlikely that a certain amount of gastritis, resulting from the swallowing of fetid pus from the ulcer on the tonsil was a necessary preliminary to the pneumococcic invasion of the gastric mucous membrane. The paper closes with some remarks on the infection of mucous membranes by the diplococcus [illegible] Friedlander has very [illegible] [illegible]ated to show that this microorganism tends to produce fibrinous exudation and destruction of surface tissue and the same tendency to extravasation of blood as when the pulmonary vessels are attacked.

Post-Vaccinal Lichen Urticatus.—R. W. Marsden reports the case of a woman aged twenty-four, who had been vaccinated one month before. History otherwise was negative. Then a feeling of itching at the former site of vaccination began, persisted for two days and was followed by a rash on the hands and arms. In general the rash could be described as of a papulo-urticarial character, the papular appearance being most marked on the backs of the hands and fingers, a feature which had naturally occasioned the suspicion of smallpox. An examination of these parts alone was, in fact, very suggestive of the disease. There was, however, no rash on the face, no accompanying pyrexia and no history of recent acute illness. The papules, which were also present on the feet, were bright red in color, about one or two lines in diameter, circular, and faded on pressure; they were softer than those met with in variola, and exhibited a tendency to run together in patches. On the palms and palmar aspect of the fingers they formed bright red discrete tender macules, not raised but still round, and especially in the former situation were as much as from two to three lines in diameter. On the arms and legs the spots were soft, flat-topped, in general rather of an urticarial character, varying in size from one to three lines, and everywhere accompanied by itching. Many spots had a narrow inflammatory areola, but the surrounding redness and œdema were best marked on the pinnæ. In the center of a few there was a minute scab, and on the surface of some others an appearance as though vesiculation was beginning, but both of these manifestations were attributed to the scratching, squeezing, or rubbing to which the patient resorted on account of the irritation. The further course of the eruption was absolutely unlike that of variola as there was no steady progress to vesiculation and pustulation—on the contrary, the spots tended to coalesce over considerable areas, forming a uniform erythema, and then faded.

British Medical Journal, April 12, 1902.

Urticaria Acuta.—Frederick S. Palmer reports two cases of this nature which have fallen under his observation which seem to be due to the eating of stewed rhubarb. The patients were both children. The type of the affection was severe and lasted three or four days. The convex elevations, with their pink areolæ, were scattered all over the body, but chiefly on the limbs. The irritation was intense. There was marked facial erythema, with a decided rise of temperature on the third day. The distressing symptoms were relieved by a dose of castor oil. No albumin was discovered in the urine.

Five Cases of Moniliform Hair, Associated with Alopecia Areata.—David Walsh describes the congenital condition of beaded hair known as monilethrix as one of great rarity. It is congenital and runs in families. The hair of the head is short and scanty, so that the patient is more or less bald. The eyebrows and any part of the hairy body may be affected. The writer notes several cases in which hair was found of moniliform type, although differing from the sharply-defined condition of monilethrix. In these cases the hair was not short and scanty, although alopecia patches were present. The peculiarity was found only in hairs which had turned or were turning white. It did not involve hairs on other parts of the body. The nodes were of irregular length, except in a few hairs of one case, which showed a fairly uniform beading, and the pigment had no distinct relation to the internodes—unlike monilethrix, in which the pigment is found gathered in the internodes, according to the writer. These cases suggest that a moniliform condition of the hair may be acquired and associated with alopecia areata.

Observations on a Series of Cases of Fracture of the Semilunar Cartilages of the Knee, Together with Other Cases of Operation for Loose Cartilage.—A. W. Mayo Robson states that in cases of rupture or fracture of the cartilages of the knee, although after replacement by manipulation, rest and ordinary treatment soon relieve, and if persevered in long may cure, yet in many of the cases relapses occur so frequently that relief by surgical treatment has to be sought. The operation is one of the simplest—an oblique incision is made from the inner border of the lower end of the patella downward and backward, down to and through the synovial membrane, so as to open the joint freely without dividing either the ligamentum patellæ or the internal lateral ligament of the knee. If the external cartilage be displaced, then the incision is, of course, on the outer side of the joint. On retracting the edges of the incision and flexing the knee the displacement at once becomes manifest. To seize the loose portion of cartilage and snip it off by means of scissors is the work of a few moments, after which the synovial membrane, capsule of the knee and skin are separately sutured. The whole operation is carried out under the strictest asepsis. It is both unnecessary and undesirable to insert the finger into the joint or to sponge the articular cavity.

Deutsche medicinische Wochenschrift, March 27, 1902.

A Large Psammoma of the Brain.—M. A. Lunz reports a case of psammoma of the brain. The patient was a woman fifty-three years of age, who for two and a half years had suffered from epileptic attacks of cortical origin. The history was a negative one as regarded syphilis and alcoholism. Slight headache was present, but it was not constant and was shifting in its location. Examination with the ophthalmoscope showed a normal retina. Because of this, together with the presence of normal pupils, and the fact that the trouble had begun suddenly and was non-progressive, the diagnosis of a new growth in the brain was thought to be absolutely excluded, and the origin was thought to be cortical and either meningeal or osseous. Accordingly, craniectomy, after Wagner's method, was performed, but nothing abnormal was found. Following the operation the patient markedly improved, and the epileptic attacks decreased in frequency for a period of some months. Subsequently, however, they regained their former intensity. Fourteen months after the operation the patient died of bronchopneumonia. At autopsy a pachymeningitis chronica fibrosa of the right hemisphere was found. Situated in the superior portion of the right hemisphere was a grayish red tumor about the size of a chestnut which upon examination proved to be a psammoma. The case is remarkable on account of the size of the tumor and the length of time which it had been present without causing any of the pathological symptoms uniformly present in new growths of the brain.

Münchener medicinische Wochenschrift, April 1, 1902.

The Treatment of Erysipelas in the "Red Room."—Herman Krukenberg reports the treatment of eighteen cases of erysipelas by means of red light, in a room especially provided for this purpose. The results obtained were very satisfactory in that the duration of the disease was greatly shortened, in thirteen being less than two days; furthermore, systemic symptoms, such as fever and headache, were rarely observed. No general or local medication was given, except in three cases, in which alcohol was locally applied. In those cases in which the local lesions were sharply defined at the beginning of the treatment such a definition began to vanish after a few hours in the "red room" and the swelling markedly decreased. Four of the cases relapsed after removal from the red light, but were speedily cured by a continuance of the treatment. The author does not think that red light in itself possesses any curative influences over erysipelas, but that the benefit derived therefrom is due to the exclusion of the chemical rays of the sunlight. The streptococcus of erysipelas does not appear to be materially injured by daylight, and the explanation of the benefit derived from red light is probably to be sought in the fact that the chemical rays irritate the skin, and make it particularly susceptible to the action of the streptococcus. It is possible that the beneficial results obtained in the local treatment of erysipelas with ichthyol, iodine, and various plasters, is principally due, to the exclusion of the light thereby. This is shown by the speedy recovery of a case of facial erysipelas, which was treated in a dark room, in which, when illumination was necessary, a red light was used. A detailed description of fourteen of the eighteen cases treated is appended.

The Surgical Treatment of Puerperal Pyæmia.—F. Trendelenburg considers the surgical treatment of puerperal pyæmia in which the general infection takes place through septic thrombosis of the uterine veins. Cases of puerperal peritonitis and general infection by the lymph passages are excluded. The surgical treatment of pyæmia was first successfully undertaken by Zaufal in 1884, who operated upon a thrombus of the transverse sinus by cleaning it out and ligaturing the internal jugular vein. Trendelenburg proposes similar procedures in puerperal pyæmia—that is, a ligature of the involved veins, and a removal of the contained thrombi whenever that is possible. Although the technique of such an operation is very much more difficult and intricate than that involved in operations on the transverse sinus, yet it is by no means impracticable. The operation is to be performed extra-peritoneally, the external line of incision being that commonly used in ligation of the external iliac artery. The best location in which to ligate the hypogastric vein is just in front of its anastomosis with the external iliac vein. When the parts are laid open it must be decided whether the spermatic or hypogastric vein, or both, are to be ligated. This is to be determined by palpation, by the means of which the location of the thrombi may be ascertained. As to whether the initial incision should be on the right or left side must be determined by bi-manual examination previous to the commencement of the operation. Often the thrombosis is bilateral. Cases in which the veins above the hypogastric and spermatic are involved are, of course, not suitable for operative treatment. A case is reported in which the operation was successfully performed and the hypogastric and spermatic veins both ligated.

The Presence of Bacteria in the Bloodvessels as a Cause of Urethral Fever.—R. Bertelsmann and Mau report the study of three cases of urethral fever, in each of which identical staphylococci or streptococci were isolated from the blood and urine. In one of the cases, a detailed description of which is given, both staphylococci and colon bacilli were obtained from the blood on the day of the initial chill; on the two following days the blood was sterile. On the fifth day the same organisms were obtained from the urine. On the sixteenth day the urethra was again dilated, and on the seventeenth staphylococci were found in the blood. On the eighteenth day both staphylococci and proteus bacilli were isolated from the blood. On the nineteenth day staphylococci were isolated, in pure culture, from the urine, and on the twenty-first from the blood, in large numbers. The patient died on the twenty-second day, under the clinical picture of a septicæmia. At the autopsy the ureters were normal. The urethral walls were thickened and scarred, but otherwise normal. The prostate was hypertrophied, but otherwise normal. Endocarditis was present, and numerous emboli were found in the liver and kidneys. The staphylococcus previously isolated from the blood and urine was obtained from the endocardial, liver and kidney lesions. Great interest attaches to the periodical appearance and disappearance of the staphylococci in the blood. It is evident that at times the body is able to dispose of an infecting microorganism successfully, but at others it is readily overpowered thereby. The authors believe that certain cases of urethral fever are produced by the systemic infection of bacteria from the urine or urethra, in which cases the microorganisms may be isolated from the blood. In many cases the infecting bacteria are quickly disposed of, but in others sepsis results. Great care should be taken in urethral dilatation, and special antiseptic precautions should always be observed. Urinary antiseptics should, whenever possible, be given previous to such dilatation. When, in spite of all precautions, urethral fever subsequently develops, all attempts at dilatation should be discontinued and other methods of treatment adopted.

Berliner klinische Wochenscrift, March 31, 1902.

Mechanical Influence of the Respiration and Circulation upon the Activity of the Body Organs.—Buttersack points out the mechanical influence of the abdominal muscles upon the activity of the abdominal organs, and shows how such activity is markedly lessened when the abdominal muscles are atrophied from non-use and disease. The movement of such muscles is directly influenced by respiration. Hence the activity of the abdominal organs is more or less dependent upon the force and character of the respiration. Respiration produces therefore a sort of automatic massage, which is an important factor in the maintenance of the physiological processes of the body. The favorable influence of massage upon pleural and peritoneal effusions has been definitely proven; that respiration in a certain measure produces such a massage cannot be denied, and its therapeutical employment should not be neglected. The mechanical effect of the circulation upon the activity of the body organs is an important factor in the maintenance and intensity of their physiological processes. The walls of the bloodvessels being elastic, the motion of the circulating blood is transmitted in a series of impulses to the surrounding tissues and organs. Such impulses act as an excitant to cell activity. The influences of this mechanism when operative within normal limits cannot fail to be beneficial; when, however, such limits are altered pathological effects result.

The Bacillus of Syphilis.—Max Joseph and Piorkowski report the discovery of a bacillus in syphilitic semen, which they regard as the probable etiological factor of this disease. Their researches were confined to the examination of syphilitic semen, since it seems certain that the causative factor of syphilis remains in this fluid long after it has vanished from other locations. Twenty-two cases of syphilis were thus examined, the lapse of time since the infection having been from five weeks to two years. In all of these a special bacillus was isolated, which is not found in normal semen or, so far as is known, in connection with any other disease. The original inoculations were made upon sterile normal placenta. After twenty-four hours growth at the incubator temperature small dewdrop colonies develop, some of which possess a grayish appearance, while others are nearly transparent. Microscopical examination shows that the latter are composed of staphylococci, while the former are made up of small rods, which have nearly the same form as diphtheritic bacilli, but are about the size of the bacillus subtilis. They stain readily with the anilin dyes. When stained they are easily decolorized by acids, and retain granis stain. The second generation of the microorganism grows well on ordinary agar, urine-agar, and blood serum. Subsequent generations, however, grow poorly, and degeneration and involution forms soon appear. The bacillus, however, resumes its original form when transplanted back on to fresh normal placenta. At first it was found impossible to cultivate the first generation upon the ordinary artificial media. Subsequently, however, this was in a measure accomplished by the use of blood serum. A peculiar feature of the bacillus is its polar staining property and the presence of metachromatic granules (Babes-Ernst bodies) in this location. Such granules are not seen in the involution forms, and are in all probability closely connected with the virulence of the bacillus. The cultural characteristics of the bacillus when grown in the second or third generation are as follows: milk coagulated and acidified, no gas formation, slight indol production, slight moist, white growth upon potato. These characteristics are best shown at the incubator temperature; they are, however, also present at the room temperature, but are more slowly developed. The sooner the semen is examined after infection the more numerous are the bacilli, nevertheless they were found in a case in which infection had occurred 5 grs. previously. This bacillus does not grow upon syphilitic placenta, and is agglutinated by syphilitic blood in at least a 1 to 40 dilution. The authors recommend the extension of observations along this line, as only in this manner can the relation of this bacillus to syphilis be definitely settled.

French Journals.

Myoma of the Leg.—Thévenot describes a tumor of the lower third of the right leg. This growth had been developing for thirty years in a farmer, aged fifty-four years. It was 10 cm. above the internal malleolus. Otherwise the patient was in good health. The tumor was absolutely painless, and freely movable under the skin and over the deeper parts, and it caused no annoyance. The patient applied caustics to cause its disappearance. This treatment produced ulceration and it became adherent to the overlying tissues. It was still movable on the lower tissues. There was pseudo-fluctuation. The excision of the tumor was very simple. It was the size of a fist and was firm, like a fibroma. It creaked under the scalpel, and when cut resembled a fibroma of the abdominal wall. The diagnosis of fibromyoma of the skin was made.—*Lyon Médical*, March 30, 1902.

Traumatism of the Brain.—Wiemuth describes these cases. In each case the skull had been fractured by the blow of a horse's hoof. In the first case there was a depression in the temporal region, in which a fist could be laid. Almost the entire frontal lobe projected. The bony splinters were removed and the parts put in place, and finally the breach was filled by means of an osteoplastic operation. The patient recovered. In the second patient there was a depression in the left frontoparietal region with contusion of the corresponding frontal lobe. For eight days after the operation the patient was unconscious and there were several clonic convulsions. When consciousness returned, there was motor aphasia, which, however, disappeared later. The patient was completely cured.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, March 30, 1902.

Tuberculous Lesions in Herniæ.—G. Chavannaz declares that the recognition of tuberculous manifestations in abdominal herniæ is of relatively recent date. The history of this affection has been established by Jonnesco. An interesting case of this nature was that of a young man, aged eighteen years. There was nothing suspicious in the family history. The personal history was negative, with the exception of an obstinate bronchitis, contracted three months before the patient entered the hospital. There was a right inguinal hernia with ectopic testicle. The hernia had existed since birth. At the operation, on opening the sac, there was discovered a certain quantity of serous liquid. The omentum enclosed in the sac was red, with some small, dry, hard granulations. Microscopical examination showed typical tubercles. This affection is rare. It can manifest itself at any age. It occurs more frequently in males. It occurs most often in cases of inguinal hernia. The prognosis seems relatively favorable if intervention is not too late.—*Journal de Médecine de Bordeaux*, March 30, 1902.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held April 10, 1902.

[illegible] G. FREEMAN, M.D., CHAIRMAN.

Sarcoma of the Lung.—Dr. [illegible] presented a [illegible] specimen of sarcoma of the lung. The child from whom it had been taken had been first seen by him in [illegible]. The family history was good. A growth occupied that part of the thorax in which the heart is normally located. The respirations were irregular and sighing, and about [illegible]. The temperature ranged from 101° F. in the morning to [illegible] F. in the evening. There were [illegible] and [illegible], and [illegible] of the lips and the mucous membranes were very pale. There was a curvature of the spine, [illegible], most marked in the dorsal region. The child had emaciated rapidly, and was suffering constantly. Dr. [illegible] examined the case with the x-rays, but although the heart could be distinctly seen on the right side, the restlessness of the patient prevented any definite information being obtained concerning the nature of the tumor. An exploratory operation was done, but the child died shortly afterward. The specimen from the tumor was examined by Dr. F. S. Mandlebaum, who reported the tumor to be a spindle-cell sarcoma in active growth. According to the literature, these growths are decidedly rare.

Vaccination Packet.—Dr. B. Van D. Hedges, of Plainfield, presented this packet. It contained a bottle of liquid soap, one bottle of alcohol, some compressed Bernays sponges, a small tube, containing sterilized needles, and some vaccination shields. The speaker said that many of the vaccination shields in the market were, in his opinion, distinctly harmful by causing constriction around the vaccination. To obviate this he made use of a simple shield, consisting of three or four layers of sterilized gauze, bound together at the end with strips of Z. O. plaster. It makes no lateral constriction while protecting the vaccination wound from the ingress of germs.

Dr. John H. Huddleston suggested that the packet should contain a sterile slip, with which to rub in the liquid vaccine, a needle not being very convenient for this purpose. He could see no objection to the vaccination shield.

Dr. R. G. Freeman remarked that it had always seemed to him desirable to use the needle for rubbing in the vaccine, because of the ease with which it could be sterilized.

Dr. F. M. Crandall objected to the shield, on the ground that considerable time must elapse for the drying of the sore before such a shield could be applied. He had been using a large corn plaster for temporary use, the patient being instructed to remove it after three days.

Dr. Charles F. [illegible] said that he had discarded the ordinary vaccination shields. He took two pads of sterile gauze, about half an inch thick, and cut out a hole in the lower pad. The other pad was then applied over this, being held in place by strips of adhesive plaster. This made a perfectly aseptic surgical dressing which could be applied without waiting for the vaccination to dry.

Dr. W. S. [illegible] said that he applied a small piece of rubber tissue [illegible] after vaccinating, and after the vaccination had "taken," and the chances of infection were then slight, all that was necessary was the application of a simple gauze dressing or shield.

Dr. E. A. [illegible], of Westfield, N. J., said that for a number of years he had been in the habit of using discs of pasteboard from which a segment had been removed. Such a disc, when moist, was readily bent into the form of a little tent and, when held in place by plaster, formed a convenient protection for application immediately after vaccination.

The Progressive Principle in Infant Feeding.—Dr. Henry L. Coit, of Newark, N. J., read this paper. He said that the [illegible] of milk [illegible] dating back to the well-known [illegible] of Meigs, [illegible] in 1882, though the profession had been especially [illegible] by the enthusiastic advocacy of percentage feeding by Dr. Rotch of Boston. The [illegible] of feeding [illegible] was [illegible]. Westcott [illegible] a method for simplifying the determination of the percentages. Many other attempts in this direction had been made since then, and many practitioners still persisted in carrying around in their pockets a copy of some complicated formula [illegible], [illegible] in a given case the physician would simply be obliged to use the [illegible] of the proprietary foods. Simpler methods of percentage feeding were demanded by the profession of to-day. It could not be denied that an enormous amount of labor was required of those who would master this [illegible]. The problem was difficult because the milk of the market is not a constant quantity. Milk could not be assumed to be an average product. It was the conviction of good observers that the violent agitation of milk by the centrifuge is detrimental. Some years ago he had suggested the use of a superfatted gravity cream of [illegible] strength, as this would greatly simplify the calculations and give accurate results. By this system approximate percentage modification could be placed in the hands of the nurse or mother. The chief points to be insisted upon were the known composition of the standards, as follows: the cream carrying the fat, the sugar solution carrying the extra sugar, and the fat-free milk or whey, carrying the proteids.

Dr. Coit then took up the subject of the progressive principle in infant feeding. It had its chief justification, he said, in the fact that the great majority of the cases we were called upon to feed were not well but sick infants, and every baby is a law unto itself with regard to its food. Every feeding case should be seen at least once a month, even when apparently well. One should begin with very low percentages and gradually increase the strength of the mixture. It was not uncommon to meet with infants of ten months taking a diet suitable for one of four months, and these children presented obvious defects of nutrition. In the feeding of premature infants weak percentages must be used, and the strength increased with the greatest caution, it being remembered that very slight changes in the composition of the milk may profoundly affect the infant. In progressive feeding there were two points to be especially considered, viz.: (1) The present capacity of the infant, and (2) the normal capacity of the healthy infant that has obtained the maximum growth. This progression should be studied carefully from birth to weaning, and it was a good plan for the physician to write out for his own guidance a series of formulæ embodying the desired progression in the given case.

The Feeding of Children During the Second Year.—Dr. Thomas S. Southworth was the author of this paper. (Vide page 656.)

Beef Juice a Sauce Rather than a Food.—Dr. Leroy M. Yale said that he was pleased that in both of these papers there had been due recognition given to the needs of the individual baby, and of the truth of the statement that there is no average baby any more than there is an average adult. The dietary should be just as carefully adjusted in the second year as in the first, even though the results of carelessness in this respect were not so immediately disastrous. He thought the tendencies of the child, as for example to gout, should be duly considered in arranging the dietary. It must be admitted that the hands of the physician were often forced by the parents' demands for an increase in the dietary. The physician looks for a distinct advantage in each change of the dietary, whereas the mother desires to add everything which will not distinctly injure her child. Much that Dr. Southworth puts in the dietary of the second year he would post pone until the age of twenty-one months, or even later. Up to eighteen months very few children take undiluted or unmodified milk with success. He believes that it is well to keep back the proteids until after this age. He entirely approved of all that had been said about fruits. He was timid about using the potato in the second year, except in those of robust digestion. The proteid value of beef juice was not equal to the standard of full milk in the same number of ounces. Its powerful stimulating effect was well known, and hence he used it as a therapeutic measure, giving it to the child when tired of milk or wearied by play to such an extent that he feared it would not take its other food. He looked upon beef juice as a sauce rather than as a food.

A Simple Method of Progressive Infant Feeding.—Dr. L. Emmett Holt said that he was quite in accord with the general principles laid down by Dr. Coit, and this was really what most people wanted. It should be remembered that the proteids must be low and the fat higher at the beginning, and that the proportions of both must be gradually increased. He did not think that Dr. Coit's method was very simple. His own method was as follows: Taking the formula, fat 3, proteid 1, and starting with milk sugar, one ounce; lime water, one ounce, and water enough to make twenty ounces, he added from time to time respectively 2, 3, 4, 5 and 6 ounces of 10 per cent. milk, giving the following percentages: fat 1, sugar 5.5, proteids 0.33; fat 1.5, sugar 5.5, proteids 0.5; fat 2., sugar 6., proteids 0.6; fat 2.5, sugar 6, proteids 0.8; fat 3, sugar 6, proteids 1.

Much trouble arose from bad habits of feeding. A meal that lasted an hour and a half with a music box accompaniment, and a nurse amusing the child and coaxing it to eat, was nonsensical, yet it was all too common. Again, it was a common complaint that the child refused cereals and vegetables, and would take only meat. All that was usually necessary was to avoid serving the several articles of food together; they should be served in courses, the meat being withheld until the child consented to take the other articles. He could not agree with Dr. Southworth as to the desirability of using the bottle in the second year. He found that such children would refuse to take milk without the bottle, so that not infrequently the parents were forced to let the child keep its bottle even when three or four years old. He preferred to teach the child to drink from a cup at the age of twelve or fourteen months. He did not approve of allowing green vegetables and potato before the age of twenty-one months. He had been very much interested in hearing what patients had to say about the criticisms made to them when abroad by English and German physicians. The English physicians were horrified at the amount of such an indigestible article as cream allowed to American babies, while on the other hand, the German physicians protested vigorously against the free use of beef juice. He thought one of the most common mistakes with cereals was in the matter of cooking. The popular cereals were those which are said to require only a few minutes' cooking, but he was in the habit of instructing his patients to cook these four or five times as long as the directions stated, and in order to do this and have the cereal ready for breakfast it must be cooked the night before.

Dr. F. M. Crandall said, regarding the feeding during the second year, that the laity and many physicians seemed to think that at this time the child was old enough to shift for itself. His own experience had taught him to postpone somewhat the giving of vegetables, and to make the feeding of the fourteenth and fifteenth months not very different from that of the latter part of the first year. The importance of milk as a basis of the diet up to the end of the first year could hardly be exaggerated. The giving of fruit was often neglected. Orange juice and baked apple were excellent, particularly in constipated babies. Such children could sometimes be very easily managed by boiling prunes with a few senna leaves. It was very difficult to induce some children to take a sufficient variety, every proposed new addition to the dietary provoking resistance on the part of the children. Children were often fond of a monotonous diet, just as they were fond of the same music and the same toys.

Dr. Charles G. Kerley said that he was accustomed to give all his babies full milk when one year old. He was not fond of giving beef juice as a steady diet to a child, as there was a tendency for it to cause looseness of the bowel with mucous discharges. It was for this reason that he had been chary about using beef juice in cases of summer diarrhœa—indeed, he had stopped many such diarrhœas by simply stopping the beef juice which had been given temporarily as a substitute for milk. He did not like the idea of giving a meal at 10 P.M.; he stopped this after the age of fifteen months, and found that the children could eat a more generous diet and do better on four meals a day.

Dr. Henry Dwight Chapin thought there was more difficulty met with in the feeding during the first than the second year. The modification of milk must be made exceedingly simple, and our effort should be only to secure approximate percentages. Cream obtained by the centrifuge was not as fine an emulsion as that obtained by the deep-setting process of creaming—in other words, that found in the ordinary bottled milk. All that was necessary to remember was that in the first nine ounces of the top milk the fats and proteids bear the ratio of three to one, and in the first fifteen ounces of such top milk the ratio is two to one. Beginning with low proteids, they should be gradually increased to the point of digestive tolerance.

Dr. Coit said that he had been charmed with the demonstration of progressive feeding given by Dr. Holt. He believed that milk sugar should be eliminated from the milk after the age of ten months, substituting a cereal which had been boiled in an open vessel (not a double boiler) for three hours. He objected to the double boiler, because the cereal would then be subjected to a temperature somewhat less than the boiling point. He soon accustomed the child to drink milk from a cup, and gradually increased the quantity of the cereal and proteid. In this way children of eleven months were taking bread and butter, and cereal with milk. Most potatoes found in the market had been dug before fully ripe, and hence the contained starch was indigestible. This had led him to postpone the use of potato until the end of the second year.

Dr. Southworth said that he favored the use of the bottle in the second year because of the larger quantity of milk that the child would take in this way, but at the chief meals it was the rule to get the child accustomed to the use of a cup.

Maine's Jumping Frenchmen.—On the northern frontier of Maine, between the United States and Canada, there exists a class of people locally known as "jumpers." Instead of imitating actions or repeating words, the sufferers from this condition are characterized by their inability to disobey any sudden, sharp order given them. If called on to jump, they will immediately execute this act. The condition has many resemblances to the great dancing epidemics of the middle ages, and almost seems like a relic of them. Like them, it spreads like contagion; and its manifestations are similarly the result of irresistible impulses, and are displayed among a class emotionally unstable and destitute of the self-control which is necessary in a well-ordered community. These "jumpers" seem to have no control over their nerves or muscles when taken off their guard or startled in any way, and while there is a certain drollery at times in their antics, the humorous element is, to thoughtful persons, overshadowed by the tragic possibilities. A "jumper" is liable to kill a man at an instant's notice, and be no more responsible for his act than would be a mad bull or a runaway locomotive.—*St. Louis Medical Review.*

RECENT MEDICAL LEGISLATION IN NEW YORK.

The Governor having completed his disposition of the bills left with him by the Legislature, on its adjournment, it may be of interest to know what new laws were enacted and what important bills failed relative to the medical profession.

Of course, the most radical bill was the one legalizing and regulating the practice of osteopathy in the State of New York and fixing penalties for the violation thereof. This bill, the supreme effort of the Christian Scientists, met with the same defeat that has attended it for several years past. The same fate attended a bill repealing the provisions of the school law, relative to instruction in physiology, hygiene and narcotics, and, also, an amendment to the penal code providing that dentists, as well as physicians and surgeons, shall not be allowed to disclose any information which they acquired in attending a patient in a professional capacity, and which was necessary to enable them to act in that capacity.

Chapter 243 amends subdivision 4 of section 145 of the Public Health Law, relative to admission to examination in certain medical studies, so that the regents may, in their discretion, accept as the equivalent for any part of the third and fourth requirement evidence of five or more years' reputable practice, provided that such substitution be specified in the license, and as the equivalent of the first year of the fourth requirement evidence of graduation from a registered college course, provided that such college course shall have included not less than the minimum requirements prescribed by the regents for such admission to advanced standing. The regents may also in their discretion admit conditionally to the examination in anatomy, physiology, and hygiene and chemistry, applicants nineteen years of age certified as having studied medicine not less than two full years of at least nine months each, including two satisfactory courses of at least six months each, in two different calendar years, in a medical school registered as maintaining at the time a satisfactory standard, provided that such applicants meet the second and third requirements.

The same law, subdivisions 2 and 4 of section 190, was amended so that a member of the State Board of Pharmacy, if elected from the eastern section, must also be a member of an incorporated pharmaceutical society or association; and that the election of the members of the State Board of Pharmacy for the eastern section shall occur in the month of June of each year. The State Board of Pharmacy shall designate a date in said month and a place in the borough of Manhattan and a place in the borough of Brooklyn for said election, and shall give fifteen days' notice of said time and place to the societies in said section, hereinafter described. At the time and place so designated in the borough of Manhattan three members for said section shall be elected, and no person shall be eligible for election, or to vote at such election, unless he be a resident of one of the counties of New York or Westchester and a member of the New York State Pharmaceutical Association, provided he be a licensed pharmacist or druggist, or of an incorporated pharmaceutical association or society in one of said counties, whose members are required to be licensed pharmacists or druggists. At the time and place designated as aforesaid in the borough of Brooklyn, two members for said section shall be elected and no person shall be eligible for election, or to vote at such election, unless he be a resident of one of the other counties in said section, and a member of the New York State Pharmaceutical Association, provided he be a licensed pharmacist or druggist, or of one of the incorporated pharmaceutical associations or societies in said other counties whose members are required to be licensed pharmacists or druggists.

Unsuccessful efforts were made to amend the Public Health Law, as follows: A new section 191a to Article 11, relative to the adulteration of and deception in the sale of drugs, chemicals and other substances; allowing merchants and retail dealers to sell carbolic acid, laudanum, spirits of nitre and quinine in original packages put up by a regularly licensed pharmacist, properly labeled, and bearing the name and address of the pharmacist putting up the same, and may also sell the ordinary non-poisonous domestic remedies; providing that a regularly licensed and practicing physician and surgeon owning and conducting a drug store in connection with his practice as such shall be entitled to a license as a pharmacist or druggist pursuant to the provisions of this article, upon presenting to the State Board of Pharmacy satisfactory proof that he is legally and regularly authorized to practice as a physician and surgeon according to the laws of the State of New York.

In town boards of health, by Chapter 939, the citizen member shall be appointed biennially, instead of annually, as hitherto, but a bill failed to pass requiring local boards of health to enforce general vaccination of all persons when required to do so by the State Commissioner of Health, who was authorized to make such a requirement when in his judgment such action was necessary for the protection of the public health; as did, also, a bill providing that in all buildings and institutions owned, maintained, or controlled by the State, the plans for all water supply, sewerage, sewage disposal and garbage-disposal works, shall be subject to the approval of the State Commissioner of Health before being adopted or constructed.

The Public Health Law was amended, Paragraph 4 of Section 166 of Article 9, so that any person who then being a bona-fide student of dentistry in this State under private preceptorship, was entitled to file on or before the 31st day of July, 1895, with the secretary of the State Dental Society a certificate of study under private preceptorship may at any time prior to the 1st day of January, 1904, upon sworn proof of such fact, file such a certificate with the regents, and thereupon be admitted to examination before the board.

These general amendments to the Public Health Law failed—regulating the sanitary condition of bathing establishments, relating to the filing of vital statistics with the county clerks, and relating to the discharge of sewage, and other waste refuse matter, into the waters of this State.

These efforts "to protect the public health" did not become laws—requiring the odorless consumption of garbage in every city, forbidding any person, association, corporation or company to sell, offer for sale or dispose of any proprietary or patent medicine or tonics, snuff, tobacco or headache, catarrh, or hay fever remedy having in it or containing cocaine; exempting from the law relative to poison physicians' prescriptions where such prescriptions are marked poison or for external use, and chemicals or acids used in the arts or in manufacturing if sold in quantities of one pound or more; prohibiting the gathering of glass or stone bottles from any public dump or garbage barrel;

making it a misdemeanor if any person distributes any free trial or trial samples of any medicine, drug, or chemical compound, by leaving the same exposed upon the ground, sidewalk, porch, doorway, or in any other manner that children may become possessed of the same; providing for a commission to investigate the nature and value of vaccination, anti-toxin, seropathy, and other alleged prophylactics, and to repeal Sections 200 and 201 of the Public Health Law; making more strict requirements in the law authorizing and empowering the State Board of Health and local boards of health to require vaccination or revaccination.

A law was passed providing for the construction of a building for hospital purposes and acquiring land for the same in the borough of The Bronx in the city of New York, the expense not to exceed $300,000. Another law provides for the reorganization and reincorporation of the Syracuse Women's Hospital and Training School for Nurses,and for a change of its corporate name to "Syracuse Hospital for Women and Children." Still another law authorizes the acquisition by the United States of lands in Erie County as a site for a marine hospital.

An important bill relative to the liability of hospitals, which did not pass, provided that no hospital incorporated under the laws of this State, sustained in whole or in part by charitable contributions or endowments, shall be liable for the neglect, carelessness, want of skill, or for the malicious acts of any of its officers, agents, or employes, in the management of, or in the care or treatment of, any of the patients or inmates of such hospital. It shall not be lawful for any such hospital to make or enter into any agreement whereby liability shall be incurred for such neglect, carelessness, want of skill, or malicious acts, and any such agreement shall be void. Nothing herein contained shall be so construed as to impair any remedy, under existing laws, which any person may have against an officer, agent, or employe of any such hospital for any wrongful act or omission in the course of his official conduct or employment.

Other hospital bills that failed were these: making eight hours a day's labor in the public hospitals of the city and county of New York; amending the act to establish a State hospital in some suitable location in the Adirondacks for the treatment of incipient pulmonary tuberculosis, in relation to the reception and maintenance of free patients; reappropriating $50,000 heretofore appropriated for establishing a State hospital for the treatment of incipient pulmonary tuberculosis; for the relief of the German Hospital and Dispensary in the city of New York, and to authorize a change of a lease from the mayor, aldermen and commonalty of the city of New York to the German Hospital and Dispensary in the city of New York to a grant, and to authorize the sale or leasing of the said property by the German Hospital and Dispensary in the city of New York; authorizing the city of Buffalo to issue $50,000 in bonds for the purpose of purchasing land as a site on which to erect a quarantine hospital; incorporating the Masonic Temple and Masonic Home and Hospital Association of Brooklyn, with Claudius F. Beatty, Walter T. Bennett, George G. Brown, John H. Brennan, Charles H. Cox, Elbert Crandall, Theodore E. Green, Richard Goodwin, Philip Herrschaft, Edwin F. Howell, Frank E. Haff, Robert J. Kenworthy, P. Frederick Lenhart, Andrew B. Martin, John T. Pinches, James H. Rollins, John Stewart, Horace Sawtelle, John E. Sparrow, Rufus L. Scott, Jr., Oliver E. Stanton, Alfred Sims, John B. Sabine, Josiah Smith, and Walter F. Sykes as the incorporators

Medical Items.

Native Medicine in Annam.—According to a writer in the [illegible] for January, no native of Annam is allowed to practise medicine or surgery unless he has studied under a recognized master for at least six years; but notwithstanding this prolonged novitiate, the results, measured by Western standards, are simply deplorable. It is not that the Annamese medical students are accused of abnormal illiteracy or of extreme stupidity; on the contrary, they are said to be very industrious and, according to their lights, by no means devoid of intelligence. From their earliest days, however, they become imbued with the grossest superstitions, accompanied by a firm belief in astrology, and, naturally, it is next to impossible for genuine knowledge to attain to any useful dimensions in the midst of such exuberant [illegible].

The Annamese pharmacopœia is made up of an immense number of exceedingly complex formulæ, and before the simplest of the medicaments can be prepared the compounder has to perform the most perplexing ceremonies in order to insure its efficacy. Among metals gold, silver, and iron are in high repute as remedies, but the writer does not make the mode of their administration clear. Iron, he tells us, is used for wounds caused by cutting instruments. In the same connection it may also be noted that iron is employed for stimulating [illegible] as well as for assisting parturition. In the latter case, however, the attendant nails the metal to the threshold of the patient's room.

Earth is freely administered in many diseases. When freshly scraped up [illegible] it is believed to cure paralysis, [illegible] and [illegible], and it is likewise thought capable of preventing the crying of infants in utero. As a cosmetic little earth is freely consumed by well-to-do people throughout the country, but all [illegible] acknowledge that it has no tonic or nourishing properties whatever. [illegible] recommends it for the practice, but [illegible] have been known to declare that the [illegible] on the tenth [illegible] hair at [illegible] over.

The Annamese do not hesitate to consume the flesh of cattle that have died from infectious diseases, and [illegible] have died from cholera or [illegible]. Hydrophobia in Annamese estimation can be communicated to a human being if a mad dog should [illegible], but happily the liver of the animal is a sovereign cure. The "stercoraceous" remedies used by the Annamese are more repulsive, if possible, than those of the Hon. Robert Boyle, but, on the other hand, it is pleasant to find that strawberries fortify the five organs of [illegible], cure consumption, and restore [illegible].—*Lancet.*

An Epidemic Among Birds.—The Treasury agent states that during the past season an epidemic has prevailed among the [illegible] of the Pribilof Islands and that the birds which are found there in vast numbers have perished by thousands. The first indication of disease was the presence of birds about the village of St. Paul close in shore, so weak that they were readily taken by children. Later dead birds washed ashore in such numbers that 212 were counted in 150 yards, while steamers from St. Michael's reported passing through large quantities of dead birds. This recalls the [illegible] which [illegible] prevailed among the Cormorants at the Commander Islands, greatly reducing their numbers.—*Science.*

Deaths in Michigan in 1901.—The total number of deaths from all causes during the year 1901 was 33,545 as compared with 33,220 during the year 1900. Death rates per 1,000 population were 14.0 and 13.9 respectively. These numbers include still births. There were 1,50[illegible] still births registered in 1901 and 1,433 in 1900.—*Michigan Monthly Bulletin of Vital Statistics.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended April 19, 1902:

INOPERABLE ROUND-CELLED SARCOMA OF THE UPPER JAW WITH METASTASES SUCCESSFULLY TREATED WITH THE MIXED TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS.

By O. K. WINBERG, M.D.,
LAKE PARK, MINN.
WITH COMMENTS BY WILLIAM B. COLEY, M.D., OF NEW YORK.

A. Y., aged forty years, born in Sweden, veterinary surgeon, with good family history, and in excellent health, was struck over the right superior maxilla by the horn of a bull in the beginning of February, 1901. Two or three weeks later he had severe pain over the site of the injury, and to relieve this the canine tooth was pulled. The pain continuing, the patient went to St. Paul the middle of April and consulted Dr. J. E. Schadle, who made a diagnosis of sarcoma. The first bicuspid tooth was pulled and the antrum explored without any evidence of an abscess being found. Excision of the upper jaw was proposed, and the patient consenting to this, the operation was performed on May 9 by Dr. C. K. Wheaton of St. Paul, assisted by Drs. Rogers and Dennis. A letter from Dr. Rogers to Dr. Coley, describing the operation, states: "There was found a large tumor involving the antrum and almost the entire upper jaw. Ferguson's incision was made, but an attempt to remove the entire growth proved unsuccessful. Thorough curetting and cauterizing of the remaining portions was done. There was also a mass the size of a hen's egg underneath the ear on the opposite side. This was completely removed. The patient having recovered from the effects of the operation, returned to his home, Lake Park, Minn., on May 17, partially relieved from the pain." After a few days the sarcomatous growth again began to increase in size, invading the nose and extending along the palate into the pharynx, and also involving the parotid region. On June 25, he again went to St. Paul and consulted Dr. Schadle, under whose care he remained until July 18. Only palliative measures, however, were used to relieve the patient's deplorable condition. In a letter to Dr. Winberg, dated July 13, 1901, Dr. Schadle states: "I want to apprize you of the fact that my prognosis is very unfavorable. It will only be a matter of time with him. All I am able to do is to make him as comfortable as possible. The disease is undoubtedly sarcoma and will eventually destroy him." Before returning home the patient consulted Dr. Geo. D. Haggard of Minneapolis, remaining under his care from August 1 to 11. In a letter to Dr. Winberg, dated August 11, 1901, Dr. Haggard states: "On August 10, I took a section of the tumor and it was found to be spindle-celled sarcoma." Dr. Haggard further stated that the patient had difficulty in retaining food and also in obtaining action of the bowels. Dr. Haggard advised a trial of the Coley toxins, although others had strongly discouraged their use, considering the case altogether hopeless. The patient's condition in the early part of August is thus described from Dr. Haggard's notes of the case:

"From August 1 to 11 weakness was progressive. Having been able to walk daily from one to two miles, he now became barely able to walk from the door to the carriage. Pulse rose to 130. Jaundice, at first slight, became more pronounced; on the 5th of August dulness and tenderness appeared in the hepatic region. There was increase of nausea and vomiting. Stools were constipated and clay-colored; urine was dark with bile. From these conditions we decided that metastases had occurred in the liver. The condition of the face at this time was as follows: The right nasal cavity was occluded, the soft palate retracted and thickened by a tumor mass in its substance. This was ulcerated in the center, the ulcerated cavity being 1 x 1½ inches in size. The tumor extended from the right malar eminence to the bridge of the nose, with which it was even in height, and downwards to the edge of the maxilla. From the higher portion of the tumor at the side of the nose I removed a section and found it to be a large spindle-celled sarcoma. Some of this tissue I yet have. At this junction I made urgent recommendation that the patient return home and have a thorough trial with the mixed toxins of erysipelas and bacillus prodigiosus, warning him that he would only have this one narrow chance."

The patient returned to Lake Park on August 12.

The disease progressed rapidly; jaundice became more profound; the liver was enlarged. Pulse rose to 140–150, was irregular and intermittent. At this time speech became difficult to understand and the odor from the disintegrating portion of the tumor was such as to keep visitors from his room. His condition was such that I hesitated to use the toxins, but the patient still kept up his courage and muttered, "The practice of medicine is like fishing; sometimes a sucker bites and sometimes it does not. Let us try the toxins."

The first injection of ½ minim was made into the tumor on August 12, 1901. August 13, 1 minim was injected; the patient's condition grew worse. August 14, 1½ minims were given; the patient's general condition grew still worse and there was no apparent effect from the toxins. On the 15th the patient's condition was so desperate that no treatment was given. It was thought best to abandon the further use of the toxins. The patient threatened to get another physician if I would not continue. August 16, 1½ minims were again given. The urine became very scant. The patient had severe pain in the stomach and his general condition was even more alarming. On the 17th, 2 minims of a fresh bottle of Coley's mixed toxins, obtained from Parke, Davis & Co., were injected. The patient's eyesight began to fail; he had suppression of urine, and no nourishment of any kind could be swallowed or retained. The teeth had become so tightly closed that it was impossible to cleanse the mouth. The swelling underneath the left lower jaw had become the size of an English walnut, and the original tumor of the right superior maxilla had reached the size of an ordinary man's fist. August 18, pulse 155–165, weak and

urination, temperature 100.8°. At this time the patient was unable to see, and he was barely able to make himself understood. Jaundice became greatly intensified. Large doses of nitroglycerin, gr. 1-50, digitalin, gr. 1-50, strychnia, gr. 1-25, were given every four hours, as symptoms of heart failure had appeared. At this time he was in a stupor. When conscious he said that he was prepared to die and implored me to either cure or kill him. During the night of the 18th he was able to swallow a little champagne. August 19, a tablespoonful of castor oil was retained, and the dose was repeated twice during the night. On the 19th of August four ounces of urine were voided and he passed some more in the afternoon. An injection of 2 minims of the toxins was given into the abdominal wall. On the 20th, 3 minims were given, also in the abdominal wall. The patient seemed slightly improved. Daily doses of the toxins were given, always except the first three injections, into abdominal wall, the amount being slowly increased, and the improvement which at first had been very slight, became more and more marked. The jaundice gradually disappeared and was entirely gone at the end of three weeks, at which time the tumor in the left submaxillary region had also disappeared, and there was marked decrease in size in the primary tumor of the right superior maxilla. Improvement in general health was rapid and continuous. The toxins were kept up in large doses up to January 4, 1902, in all 103 injections having been given—twelve in August, twenty in September, twenty-one in October, twenty-two in November, twenty-four in December, and four in January. The toxins were always diluted with 15 cc. of water. The dose was increased as rapidly as the patient could possibly bear it. As an illustration of the marvelous rapidity of his recovery, may be mentioned the fact that on August 27 steadied by a cane he walked to the gate of his place and removed a splinter from a horse. His weight at the time when the treatment was begun was 113 pounds. September 4, he weighed 124 pounds and had a voracious appetite. September 12, he rode thirty miles on a professional call, and since this time has attended to a very large veterinary practice, which often calls him away both night and day. On January 4 he weighed 143 pounds. On January 12, 1902, he made a trip to New York, solely to show Dr. Coley the result obtained with the toxins. On January 13 Dr. Coley presented the patient before the Surgical Section of the New York Academy of Medicine. At that time examination showed no trace of the tumor either in the neck or face or jaw, abdominal examination showed nothing abnormal.

(Comment by Dr. William B. Coley of New York, with reports of pathologists.)

Although this patient was not treated by me personally, the treatment was carried out under my direction. I must confess that had I been consulted before the treatment was begun, I should have advised against attempting it in such a desperate and apparently hopeless case.

Aside from the extraordinary recovery of a patient so near death from inoperable sarcoma, the case is remarkable from the fact that the cure was obtained by injections remote from the tumor. Therefore, the effect upon the tumor was entirely due to systemic rather than local action. Although I have personally had a few successful cases of inoperable sarcoma in which the injections were made remote from the tumor, in nearly all of the successful cases the injections have been local, directly into the tumor itself. I have always maintained, however, that the curative action of the toxins is systemic as well as local. This case fully demonstrates the correctness of this view and disproves the position taken by a number of writers that the action of the toxins is merely local in character, of the nature of an escharotic. This case is so extraordinary that it is most important that the diagnosis should be placed beyond question. Dr. Rogers of St. Paul states that the mass removed was examined by Dr. J. L. Rothrock and pronounced sarcoma—variety not stated. It was also pronounced sarcoma by Dr. Schadle. Microscopical examination was made by Dr. George D. Haggard of Minneapolis, and the disease pronounced spindle-celled sarcoma. All agreed that it was clinically sarcoma and absolutely inoperable. In addition to the foregoing, I have submitted sections to Dr. B. H. Buxton, and Dr. Jas. Ewing, Professor of Pathology of the Cornell Medical School, who pronounced it spindle-celled sarcoma, and finally to Dr. Wm. H. Welch of Johns Hopkins University.

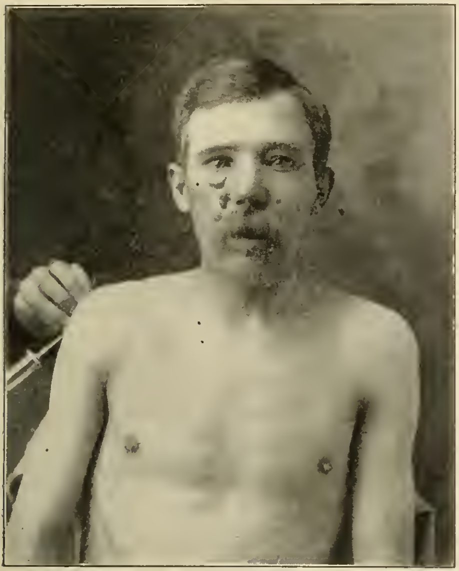

Fig. 4.—December 5, 1901.

The very complete report of Dr. Welch is given in full, and is, I think, sufficient to establish the diagnosis beyond question.

On November 27, 1901, I presented a patient before the New York Surgical Society, who had, in October, 1900, a small round-celled recurrent inoperable sarcoma of the parotid gland. This tumor had entirely disappeared under small injections (ℳss. to iij.) of the mixed toxins of erysipelas and bacillus prodigiosus, continued for eight months. The patient is still perfectly well, with no trace of tumor remaining. In this case there was a very thorough microscopical examination made by several pathologists, and the elaborate report of sections by Dr. William H. Welch will be found March, 1902, in *Annals of Surgery* (Transactions of New York Surgical Society).

These two cases, together with a report of sixteen personal cases of inoperable sarcoma, successfully treated and remaining well for periods varying from three to eight and one-half years, made before the American Surgical Association in Baltimore, May 7, 1901, would seem to be a sufficient answer to the recent statement of Dr. Conrad George of Ann Arbor (*Philadelphia Medical Journal*, January 11, 1902), that there is probably not a single well-authenticated case of cure of sarcoma by the toxin method.

Report of microscopical examination of section of tumor by Dr. William H. Welch of Johns Hopkins University:

"The section shows a tissue composed mostly of closely packed cells without definite arrangement. The predominant cells are fairly large oval, spherical, or irregularly polyhedral cells, with not very abundant cytoplasm, and with round or oval nuclei larger than those of ordinary lymphocytes. In addition, there are some fusiform cells and smaller cells of the lymphoid type. The cellular outlines are not readily made out. The intercellular stroma is scanty, but in places a fibrillated intercellular substance is recognizable.

"There is considerable fragmentation and distortion of nuclei, especially in certain places, and in one area there is necrosis of the tissue. Hemorrhages are present in a few places. Small acini and ducts of an acinous gland occur irregularly, distributed in different parts of the section. These are generally widely separated by intervening tissue of the tumor. They are lined by one or two layers of low cubical epithelium. Bloodvessels with definite walls are not readily made out, but vessels with an endothelial lining, immediately surrounded by the tumor cells, can be seen. *Diagnosis.*—Round-celled sarcoma of an acinous gland. *Remarks.*—There is, perhaps, enough diversity in the cells to

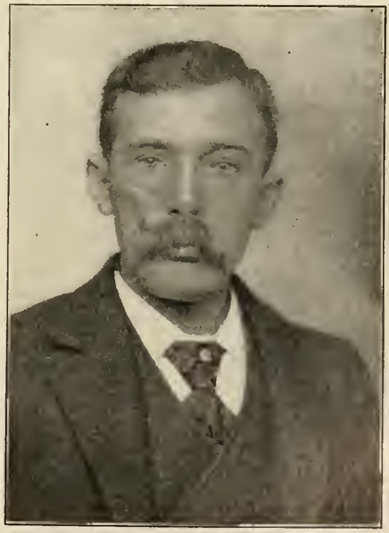

Fig. 5.—January 1, 1902.

jority the designation mixed-celled sarcoma, but round or oval cells greatly predominate. The tumor has the histological characteristics of malignancy. (Signed) William H. Welch."

THE INDICATIONS FOR THE SURGICAL TREATMENT OF CHOLELITHIASIS.*

By A. A. BERG, M.D.,
NEW YORK.
ADJUNCT SURGEON TO MOUNT SINAI HOSPITAL.

No apology is necessary for presenting to this society, composed in the main of general practitioners, a paper dealing with the therapeutics of biliary calculi. Not since the profession has had to determine and fix the indications for operative interference in appendicular disease, has a more important question been proposed than "What are the indications for surgical intervention in biliary lithiasis?"

The internists, for the most part, are still prone to rely upon medication, combined with hygienic and diatetic measures, for the treatment of attacks of biliary colic, and acute calculous cholecystitis; whereas the surgeons, lead by their repeated observance of the extensive and serious pathological changes, attendant upon long-standing cholelithiasis are urging a removal of the calculi by operative procedure, as soon as they manifest symptoms of their presence.

No one who has had much to do with this class of patients will deny the efficacy of medical treatment in certain cases; nor will anyone who has seen the extensive lesions that so frequently result from calculous disease of the gall-bladder doubt the propriety of early surgical interference in others. The question at once arises, therefore, when are we to employ the expectant medical treatment, and when the radical surgical procedures; and it is to this consideration that I desire to devote this paper.

It is conceded by all that the medical treatment of cholelithiasis brings about either: (1) An expulsion of the calculi from the biliary system: or (2) A subsidence of the disease into a latent state. A dissolving of the calculi *in situ* is acknowledged to be impossible.

It would be well to inquire apropos of the aim to bring an active type of cholelithiasis into a latent condition why it is "that individuals can carry calculi in their gall-bladders for many years with never a symtom of their presence?" For if we can understand how and under what conditions nature maintains a "state of latency" we will be better able to decide whether in a given active case this latent state can be restored, and when it is restored how it can be kept up? To help in solving this query let us turn to the pathogenesis of biliary calculi.

The formation of stones within the gall-bladder and ducts, which appears to be a transitory process for the calculi, are in the vast majority of instances of the same age (Naunyn, Hoppe-Seyler) is dependent upon two factors. (*a*) The stagnation of bile in the gall-bladder and ducts; and (*b*) The invasion of bacteria of a diminished degree of virulency into the biliary system.

The stagnation of bile in the gall-bladder is furthered by a diminished extent of contraction of the diaphragm, such as is brought about by tight lacing and thoracic breathing, and by pressure exerted on the cystic duct by neighboring viscera, *e.g.* floating kidney, or pregnant uterus, etc.

Such a biliary stasis permits of a sedimentation upon the mucosa of bacteria, which may have gained access to the gall-bladder. If these bacteria are of a high degree of pathogenicity they establish an acute inflammation of the gall-bladder, a condition that is known to accompany typhoid fever and some of the infectious diseases. Such a cholecystitis may affect an organ that has been previously healthy, or one that has been the seat of calculi. But if, as is usually the case, the invading bacteria are of a lower degree of pathogenicity they establish in the mucosa lining the gall-bladder a catarrhal inflammation which has been styled the "stone-building catarrh." This diminished virulency of the invading bacteria is due to the fact that the usual channel of infection of the biliary tract is by the bile, the organisms being excreted by the liver, where their virulency has as a rule been much lessened.

Due to this "stone-building catarrh," the epithelial cells of the mucosa undergo degeneration and desquamation. The degeneration results in the formation of cholesterin and calcium within the cells, and by their desquamation the cholesterin and calcium are liberated into the gall-bladder. The calcium there precipitates the bilirubin of the bile, and combines with it forming bilirubin calcium. The cholesterin and bilirubin calcium are then deposited around the bacteria or other foreign material within the gall-bladder and thus calculi are formed. If the "stone-building catarrh" continues, so that degeneration and desquamation of the epithelial cells constantly takes place, the calculi gradually increase in size by a continued deposition upon them of cholesterin and bilirubin calcium. But if the stagnation of the bile is relieved and the bacteria resident within the gall-bladder are either carried away by the freely circulating bile, or become encysted by the deposition of cholesterin or bilirubin calcium around them, the "stone-building catarrh" ceases and no further increase in the size of the calculi takes place. From these remarks it is evident that the formation and growth of biliary calculi are dependent upon a chronic catarrhal inflammation of the mucosa lining the gall-bladder.

It is well-known that an inflammatory process increases the "irritability" of the affected part. When, therefore, the biliary mucosa continues to be the seat of a catarrhal inflammation, or when a reinfection of the biliary passages reestablishes an inflammation that had subsided, the increased irritability of the mucosa, induced by such inflammation, makes it more sensitive to the foreign bodies, such as calculi, that come in contact with it. This increased sensitiveness of the lining mucosa causes the pain in the gall-bladder and stimulates the viscus to expel these foreign and irritating bodies. If the attempt at expulsion is successful an attack of biliary colic is produced. It is to be especially noted in this connection that no fever and no local inflammatory reaction of the gall-bladder accompanies such pain or colic.

With the re-establishment of a free biliary circulation, and the encystment or expulsion of the calculi, there results a return of the lining mucosa of the gall-bladder to its normal state, and a consequent diminution of its sensitiveness. The calculi present within the gall-bladder no longer act as offending and irritating bodies, and the disease is said to be in a latent state. Here then is the explanation of the latency of calculi, and also of the cholecystitic pain and colic.

Nature brings about a latent state by restoring a free circulation of the bile and by the expulsion or encystment of bacteria within the gall-bladder, thus relieving the catarrhal inflammation of the mucous membrane lining this viscus. If we desire to reduce an active form of biliary lithiasis to a state of latency we must immitate the processes of nature. Furthermore it is to be especially noted that natural latency only takes place in a gall-bladder that is unaltered, except for the catarrhal inflammation of the mucosa. We must not expect, therefore, by our artificial methods to be able to bring about a latent state in a gall-bladder that is the seat of extensive pathological change. To establish a latent condition of the disease we rely upon the administration of alkaline waters, salicylates, and hydrogogue cathartics, together with proper diatetics and exercise. Much and lasting good results can be obtained from such treatment in those cases of calculous disease that manifest themselves only by cholecystitic pain and uncomplicated attacks of biliary colic.

---

*Read before the Eastern Medical Society, New York.

Occasionally, however, in spite of the exhibition of such treatment, the pain continues and the attacks of biliary colic repeat themselves at frequent intervals. This indicates that the catarrhal inflammation of the mucosa has not been relieved. When from the severity of the pain, or the frequency of the attacks of colic, the individual becomes invalided and incapacitated for work, it is folly to persist along this line of treatment, when by a simple and safe operation the calculi can be removed and the inflamed mucosa healed. Such severe cholecystitic pain, or oft-repeated uncomplicated attacks of biliary colic, persisting in spite of the exhibition of proper internal medication with general diatetic and hygienic treatment, form the first indication for surgical intervention.

I have repeatedly made reference above to the phrase, "uncomplicated attacks of biliary colic," and it would be well here to define my meaning. As an attack of biliary colic is due to the attempts on the part of an irritable viscus to expel an offending foreign body, it should give rise only to pain, and the reflex symptoms depending upon the irritation of the sensitive nerves, the foreign body comes into contact with in the gall-bladder and ducts. Fever is always absent; in fact, the temperature is apt to be subnormal. The earliest and, perhaps, most frequent complicating symptoms of an attack of biliary colic are a rise of the temperature and distension of the gall-bladder. The interpretation of these symptoms is that an acute inflammation of the gall-bladder has taken place. Such a cholecystitis is due to a secondary invasion of the biliary system by virulent organisms. These latter reach the gall-bladder either from the intestines, in which case they are apt to be of the colon type, or are conveyed to the gall-bladder with the bile, being excreted by the liver, from the blood, in which case they are usually staphylococci, streptococci, or typhoid bacilli, or they may be directly conveyed to the gall-bladder by the circulating blood, this being probably a very infrequent method of infection.

The presence of such virulent bacteria in the gall-bladder, together with stagnant bile and calculi, provokes an acute inflammation of this viscus, to which the febrile process and distension of the organ are due.

The intensity of the local inflammatory reaction, and of the general toxæmia, vary in different cases. The mildest local reaction is a catarrhal inflammation of the mucosa of the gall-bladder, with serous effusion into its cavity, thus giving rise to an acute hydrops. Purulent, or gangrenous inflammation of the mucosa, accompany more intense types of infection, whereas the extension of the inflammation to the entire wall of the gall-bladder, to the bile ducts and their ramifications in the liver, to the peritoneum, to the liver itself, represent the most serious lesions that follow upon such a secondary or mixed infection of the gall-bladder. The mildest or most severe of these local pathological changes may accompany the very first indications of gall-bladder disease, as is well indicated by the following history:

Brune L., sixty years old, admitted May 11, 1900. Never had any previous attacks of biliary colic; never had been jaundiced. The present illness was of three days' standing. It commenced with sudden onset of pain in right hypochondrium. The bowels moved once after the onset of the illness; the color of the stool was not noticed. On admission the patient was not icteric; the temperature was 100.6°, pulse rate 126. There was a very large mass in the right iliac and umbilical regions, very tender to pressure. The gall-bladder region was not tender. This mass was everywhere surrounded by tympanitic resonance. The diagnosis was not positive on account of the low situs of the tumor, and its separation from the liver by an area of tympanitic resonance.

Immediate operation under local anæsthesia. Peritoneum was found much œdematous. In the right iliac fossa was an extensive fibrinous exudate, which led upward to the liver. This exudate covered over the gall-bladder, which was much enlarged, and led downward to the iliac fossa. The gall-bladder was isolated, aspirated of its purulent contents, then incised, and two large stones, the size of walnuts, removed. There were no other calculi in the ducts. Drainage and part closure of the abdominal wound. Uneventful convalescence.

It is the rule, however, that the severest forms result from long-continued bacterial action upon the biliary apparatus.

The general toxic symptoms accompanying such an attack of acute cholecystitis are rarely of an alarming character, and this is explained by the structure of the gall-bladder. For this viscus is a highly elastic organ, capable of considerable distention. It can, therefore, accommodate considerable quantities of the products of inflammation and of bacterial life and development, without these latter being under any marked tension. Inasmuch as it is the tension of the confined inflammatory and bacterial products that decides the rapidity of an amount of resorption, it is quite evident that the foudroyancy and degree of general intoxication will be, as a rule, of a low type in gall-bladder inflammations. It is to be noted, however, that as repeated attacks of cholecystitis result in alterations of the wall of the gall-bladder, the normal elastic tissue being replaced by dense cicatricial structures, its distensibility is gradually reduced, and hence the constitutional symptoms become more marked with each new attack of acute inflammation.

With the subsidence of the evidences of local inflammation and general toxæmia, it is usually presumed that the mischief produced by the invading bacteria is at an end. Unfortunately, such is not the case. For the bacteria that have secondarily gained access to the gall-bladder are rarely expelled from this viscus. Just as bacteria remain for long periods in the medullary cavity, and in the epiphyseal ends of the long bones, so do virulent bacteria that have secondarily infected the gall-bladder and ducts remain in these viscera. And, further, just as we find the bacteria in long bones, exciting, from time to time, fresh attacks of acute osteomyelitis, so do these bacteria in the gall-bladder excite, from time to time, fresh attacks of acute inflammation. In the interval between each attack they are not inactive or dormant, but all the while they are producing marked local changes, and elaborating their toxins, which are being gradually absorbed into the circulation, and carried to the various organs of the body, there producing the characteristic lesions of chronic septic intoxication, as manifested by fatty degeneration of the liver, spleen, kidneys, heart, etc. In substantiation of this I desire to call attention to the lesions frequently found in patients who have died from shock a few hours after an operation upon the biliary system of structures for long-standing cholelithiasis. As typical, I quote here the history and pathological findings of a case recently operated upon by me, in the surgical service of Dr. Gerster, at Mt. Sinai Hospital:

Betty L., thirty-one years old, admitted September 2, 1900. The patient had repeated attacks of biliary colic with cholecystitis for six years. Jaundice usually followed the attacks; on admission, the patient, an exceedingly obese woman, weighing three hundred pounds, was suffering from such an attack of colic with cholecystitis. Temperature was 101°, pulse rate about 100. The marked obesity made palpation difficult, but in the gall-bladder region could be felt a hard tender mass underneath the liver. Urine was negative. September 3, cholecystectomy. Numerous adhesions covered over a very deeply-seated gall-bladder. The gall-bladder was of hour-glass shape. Exposure of the viscus was exceedingly difficult on account of the great thickness of the abdominal walls and its deep position. The gall-bladder was aspirated of its purulent contents and then incised. Its lumen was divided off into three compartments, each of which contained calculi. The marked changes in the gall-bladder necessitated its extirpation, as proper drainage of its cavity was impossible. The dissection of this viscus from the liver was again very difficult, and had to be done entirely by the sense of touch. The cystic duct was fully ten inches from the surface and high up underneath the liver. Palpation of the hepatic and common bile ducts was made, but it was impossible to gain access to the retroduodenal part of the choledochus. Gauze tamponade of the bed of the gall-bladder, drainage and closure of part of the abdominal wound. The operation lasted two hours. Reaction was not good. In the early morning of the next day the pulse became very rapid and the temperature rose to 104°. No signs of peritonitis. The pulse gradually became more rapid and feeble, the temperature rose to 106, and death ensued twenty-four hours after operation. The urine after operation contained 2½ per cent. albumin and many casts.

Post-mortem.—Liver was congested and soft, and showed fatty and acute degeneration. In the retroduodenal portion of the choledochus were two freely movable stones, one of which had caused an ulcer of the mucosa just above the papilla.

Kidneys.—Very large and soft; capsules adherent.

Spleen.—Soft and pulpy, and very large.

Peritoneum.—No indications of peritonitis.

It is this chronic septic condition that renders these patients so susceptible to shock, and accounts for their frequent collapse after even the simplest operative interference upon them.

Not to be compared to the cloudburst that spends its energy in the lightning flash and thunder peal, and leaves the skies clear and bright after its passage, is the acute attack of cholecystitis. For the acute inflammation is replaced by a chronic one whose continuance is favored by the calculi and stagnant bile. As a result of this chronic inflammation extensive alterations take place in the structure of the gall-bladder and bile ducts. Such changes are, ulceration of the mucosa, followed by cicatrization and resulting stenosis of their lumens; fibrous degeneration of the walls of the organs, with resulting contraction and dilatation, chronic adhesive peritonitis uniting the biliary structures to the pylorus, intestines, omentum, and liver; deep ulcerations of the entire wall of the gall-bladder with perforation into the peritoneal cavity or neighboring hollow viscera, thus establishing preternatural orifices of communication with these hollow organs. Together with these changes the gall-bladder and ducts become filled with the products of exudation, serum, seropus, pus, shreds of gangrenous tissue and stagnant bile, and from the ulcerated and inflamed mucosa a continuous resorption is going on, thus giving rise to chronic toxæmia, and producing waxy and fatty degeneration of the spleen, liver, kidneys, etc. These alterations are not the result of repeated attacks of acute inflammation; they are the changes that result from long-continued inflammatory processes. The exacerbations called forth, either by a fresh invasion of bacteria or by a renewed virulency of the bacteria already resident within these structures, only add to the local lesions and general toxæmia.

In view, then, of these facts, the writer maintains that the first attack of cholecystitis, accompanying calculous disease of the gall-bladder or ducts, calls for the abandonment of the medical treatment and a resort to surgical intervention in order to remove the calculi and cure the cholecystitis.

As to whether the operative interference should be undertaken during the acute attack, or in the quiescent period after the acute seizure, depends upon the intensity of the local lesions and the severity of the general toxæmia.

It has been the custom in dealing with acute attacks of appendicitis to determine the question of immediate operative interference by a consideration of the pulse rate, temperatures and local rigidity of the abdominal muscles. It would naturally be supposed that the same considerations would guide us in deciding whether or not to operate at once in acute calculous cholecystitis.

Such is not the case, however, and a reference to the anatomical structure of the two organs will at once explain why. The wall of the gall-bladder is very rich in elastic tissue, this permitting to the viscus considerable distensibility. The appendicular wall, however, is very poor in elastic tissue, and in consequence but little expansion of the lumen is possible. It is evident, therefore, that when the orifices of exit of these viscera are respectively closed, the elasticity of the former permits of its accommodating even large amounts of inflammatory exudation without these latter being under much tension.

In the appendix, on the other hand, the tension rapidly rises when even small quantities of exudation and bacterial products accumulate within its lumen. As it is to the rapidity of rise and the degree of the tension that the severity of the local and general manifestations are due, it is clear that the symptoms will be much more marked in appendicular than in gall-bladder affections. For the greater the rise in tension the more will be the amount of absorption of toxins from the inflamed viscus, and hence the higher the temperature and pulse rate, and the higher the pressure within the viscus, the greater will be the stretching of its walls, with consequently the more local pain and muscular rigidity. It is, furthermore, evident that whereas the highly-tensioned contents within an occluded appendix strongly favors perforation of its walls, the absence of such pressure within the gall-bladder renders this complication rather infrequent.

It is fair to expect, therefore, in gall-bladder lesions a relatively less intense character to both the local and general symptoms than is found in diseases of the appendix, and this is the reason why urgent operative intervention during the course of an attack of acute cholecystitis is comparatively unusual. It is only when the inflammatory process is very intense and characterized by high temperatures, or when there are large accumulations of inflammatory products within the gall-bladder; or when the bacterial infection spreads to the ducts and their ramifications in the liver, as is likely after repeated attacks of cholecystitis, that immediate operative interference must be resorted to.

The rule is for the first attack of acute cholecystitis to subside spontaneously. It recurs after a shorter or longer period of apparent quiescence. During these latent stages a continuous toxic resorption is going on, which gives rise to degeneration of the other organs of the body. With each renewed attack the toxæmia is increased and the local lesions augmented. The individual becomes emaciated and weakened, the gall-bladder, bile ducts and liver the seat of serious and extensive lesions; obstructive jaundice develops, and, finally, an infective cholangitis, which puts an end to the long sufferings of the miserable patient.

In view, then, of the constant changes that are taking place in the gall-bladder and ducts, which are the seat of calculi, when a secondary or mixed bacterial infection has once taken place, and in view of the gradually increasing toxæmia, resulting from a continued resorption of the products of bacterial life and development, with the deleterious effects upon the other organs of the system, are we justified in waiting until the last stages of the disease before proceeding to surgical treatment? Are we justified in waiting until that period when, from the numerous adhesions around the gall-bladder and ducts, the operations are rendered very difficult and of long duration? When the surgeon is compelled to remove the gall-bladder, or split open the ducts, and establish drainage of the latter on account of the extensive changes in the organs of the biliary system—procedures that become even more serious and taxing to the patients on account of their chronic sepsis.

It is the opinion of the writer, in view of our advanced knowledge of the pathogenesis and pathological lesions of calculous disease of the gall-bladder, that delay and procrastination to the later stages of the disease, before invoking the surgeon's aid, is unjustifiable and unwarranted. Operations undertaken at these periods are not operations of our choice, planned under favorable conditions; they are compulsory upon us, at any time of the day or night, in order to save the life of the patient, and the resulting mortality is proportionally high. For, just as in appendicitis, the interval operation, to remove a chronically-diseased organ, which contains no pus, and is not perforated, is a simple task, attended with but a very slight mortality, so is the early operation for removing stones from the gall-bladder comparatively simple, and attended with but 2 to 3 per cent. of deaths. But complicated and difficult as are the operations for perforated gangrenous appendicitis, with abscess formation, and diffuse peritonitis, just so are the operations upon the biliary system difficult and laborious when there are extensive peritoneal adhesions, with pus and impacted calculi within the gall-bladder and ducts; so are they deeply shocking to the patients, and followed by a high mortality, a mortality that is still further increased should there be multiple abscesses in the liver, cholæmia, or deep jaundice; even the great master Kehr having over 50 per cent. of deaths in these cases.

In my remarks this evening I have endeavored to bring some order out of the confusion that still exists regarding the indications for the employment of the medical and surgical treatment of biliary lithiasis. My conclusions may be stated as follows:

a. Indications for Medical Treatment.—Cholecystitic pain or attacks of biliary colic, in either case unattended with fever.

b. Indications for Surgical Treatment.—(1) Operations of choice—undertaken in the quiescent period; with the object of avoiding serious complications. a simple procedure, and followed by 2 to 3 per cent. mortality. (*a*) Severe cholecystitic pain, or oft-repeated uncomplicated attacks of biliary colic; persisting in spite of medical treatment. In virtue of which symptoms the patient becomes invalided. and incompacitated for work; (*b*) After the first attack of acute cholecystitis, associated with fever.

(2) Compulsory operations—undertaken at any time of the day or night; often amidst unfavorable surroundings, and in patients who are septic, emaciated, and of low vitality. Difficult and laborious procedures, and attended with high mortality—50 to 75 per cent. (*a*) Foudroyant and intensely acute attacks of cholecystitis. (This may be the first indication of calculous disease, but usually follows previous milder attacks.) (*b*) Hydrops, empyema, gangrene, or perforation of the gall-bladder, cholæmia, abscess of the liver, and diffuse peritonitis.

FUNCTIONAL AND PARALYTIC STRABISMUS.

By D. B. ST. JOHN ROOSA, M D., LL D.
NEW YORK.

Although our knowledge of the etiology of strabismus leaves much to be desired, it cannot be denied that we are making good progress in the successful treatment of this distressing deformity, and in a better understanding of its nature. It is now thoroughly settled, thanks to the pioneer work of Javal, and in spite of the doubts of certain authorities, that there is, at least, a small, and perhaps a large, proportion of cases in which the amblyopia, dependent upon incorrect position of the macula and disuse of the eyes, may be wholly or in part removed, and that in a certain contingent of cases. binocular single vision may be produced by treatment. The curative value of the exclusion of the better eye in strabismus, for the sake of exercising the amblyopic eye,[1] is again demonstrated by Dr. Derby's paper in the Medical Record, and in several that have preceded it, especially that of Dr. A. E. Davis, read before the American Medical Association, in 1901,[2] and is of great importance. Although at one time sceptical as to the results to be obtained, I have had a few striking cases of this kind in my own practice, which have been fully reported. The importance also of attempting to cure the strabismus by treatment with glasses, before an operation is undertaken, has also been fully shown by the later writers, since Javal here also led the way. While the hopes as to cure, by means of securing paralysis of accommodation by the use of atropin, without complete correction of the refractive error, have not been realized, we have, by the proper correction of the astigmatism and hypermetropia, usually found in convergent strabismus, reduced the number of cases to be operated upon by quite a large percentage. Davis[3] thinks this is 50 per cent, and with this view I fully agree. The profession having an interest in ophthalmology already knows from my writings on the subject, that I believe we have already made a great advance in the kind of operation to be performed, and that I now invariably, for non-paralytic or functional strabismus, divide both the interni in convergent strabismus and both externi in divergent strabismus, having stretched them before the division is undertaken, according to the rules laid down by Panas, who first suggested and performed this operation.

It is not very long since the existence of any cases of amblyopia as a result of the squint was denied. The two cases of Dr. Walter B. Johnson[illegible] and of one of my own, the latter quoted by Javal in his monograph on Strabismus, prove that this is occasionally the case at any rate. Whether or not it is always so, perhaps remains an open question. It is my opinion that there is a certain proportion of cases in which the amblyopia precedes the strabismus, and is one of the factors producing it. This is certainly true of the strabismus often seen when one eye has been operated upon for cataract, while the other is left amblyopic. Again, a high degree of hypertropic corneal astigmatism, or a high degree of myopia in one eye, might be a cause of amblyopia at birth or during infancy. Some of the former scepticism was due, I think, to the fact that strabismus was in many quarters supposed to be an effect of the weakness of the muscles, and the origin was not sought beyond their action. Indeed, the muscles themselves are often examined as if they were the primal cause of strabismus. Functional strabismus is no more caused by weakness of the muscles than is nystagmus. The old error of mistaking an effect for the cause is at the bottom of the erroneous theories about the origin of strabismus. Except in paralysis, the muscles are as strong in eyes affected with strabismus as they are in eyes in a proper state of parallelism. It is only the fixation power that is weakened or lost, and that is from what may be termed central causes. I am very far from denying that a muscle may become weaker after long disuse, or after it has been divided and haggled in an operation for convergent strabismus, so that the fibers are not again united. It may then have scarcely any power. We often see this in that form of divergent strabismus depending on a failure of an operation for convergent squint. After such a muscle is fished out and advanced and reattached, I have had occasion to see the growth of its fibers in cases where the operation was repeated a year after. But what I mean to affirm is, that in ordinary functional squint, the weakness and improper action of the muscles, whether it be more or less, is due entirely to the condition back of them which causes the strabismus. This is just as atrophy or shriveling of the muscles of one side of the body may occur as the result of a central lesion which prevents the muscles from action. It would be very absurd to speak of this condition as the primary cause of the inability to walk, or to use one side of the body, since that disability resulted as soon as the cerebral hemorrhage occurred, and is as great, if not greater, the moment after the hemorrhage which produced the hemiplegia, as it is when time has allowed the unused muscles to be lax and, perhaps, become atrophied.

To speak of monocular strabismus, excepting in paralytic cases, is a glaring fault in nomenclature. Among other evidences of the elementary state of knowledge as to the nature of strabismus is the fact that so much is said directly and by inference, even to this day, of monocular strabismus "of the eye which squints," and other terms to indicate that only one eye is at fault.

I long since[illegible] endeavored to show that all functional squint is concomitant, and I have repeated this observation in other places,[illegible] and that there is, consequently, no such thing as monolateral squint where the muscle is not paralyzed. Yet even men more or less expert in ophthalmology, in my clinic, often ask me as I am about to operate on a case of strabismus, "Which is the squinting eye?" Some of these inquirers really intend to ask, "Which is the eye that, as a rule, or generally, squints?"

Panas, proposing his new operation on both muscles at one sitting, said in his article: "The conception of the unilateral character of strabismus, while it is true of the paralytic variety, or that due to contraction of the muscle, is absolutely incorrect as to that which concerns concomitant strabismus,"[illegible] and he then gave the proper name of functional to concomitant strabismus.

Not many years since, in the paper read before our State Medical Society, just quoted, I had occasion to speak of the scepticism in the minds of some of the experts in ophthalmology, as to the expediency of operating at all, or of giving very much special attention to strabismus. This scepticism was due, I believe, to the fact that strabismus had not then been everywhere thoroughly studied, as is now being done. It has given way, until all experts in ophthalmology no longer hesitate as to the proper treatment of strabismus, that is to say, in children, to first make an honest endeavor, by glasses and stereoscopic exercises, to cure the strabismus, and if this fails, in a few months, to resort to operation. In adults, or in inveterate strabismus, or in children having poor fixation, it is proper and better to operate first and continue the treatment by glasses afterward. In the days when fear of too great an effect prevented us from dividing both interni at one sitting, Agnew was wont to remark that it was immaterial as to which eye was operated upon at the first sitting. He fully realized the bilateral character of functional squint. It is interesting to note that there never was so great a fear of dividing both externi for divergent squint at one sitting as was the case with the interni.

I objected to the word "concomitant" in the definition of strabismus, for all strabismus, with the exception of paralytic squint, is necessarily concomitant; that is to say, if one causes a patient with convergent or divergent squint to fix with the squinting eye, at the same time covering the one that is *usually* in a proper position, it immediately turns in or out, under the shade, according as the squint is convergent or divergent. It is much better, in my judgment, to adopt the names of "functional strabismus," and "paralytic strabismus," as suggested by Panas, to describe the two great varieties of strabismus. Of course, the latter form may be monolateral, but the former, in the very nature of things, cannot be. The important point to be noted in functional convergent or divergent squint is as to which is the eye with which fixation is usually made. Generally, if the refraction and vision of the two eyes are of about the same degree, although there are exceptions to the rule, the subject will alternately fix with one eye and then with the other, but where there is a great difference in the error, the fixation will be habitually with the eye having better vision. Finally, and sometimes very early, if the strabismus be uncorrected by glasses or operation, the deviating eye, as is well known, in time loses in part or wholly the power of fixation.

An improper nomenclature often leads to misconceptions of the nature of an affection. It may prevent the adoption of better means of cure. Those who speak of "monolateral" squint are not only speaking against the facts of the case, but they are also preventing those whose knowledge, perhaps, is not so complete as their own from a full appreciation of the advantage of a bilateral operation for a bilateral affection. Great as was the work of Graefe in many departments of ophthalmology, that which he did in strabismus was not productive of good results. He was working on wrong lines, and he led men with less genius into error by his ideas that the squint could be better treated by what he called dosage of the operations—graduated tenotomy is a later term. This is not correct, and the theory was evidently based on the idea that a certain power of one externus or internus over that of the other was the fault that produced the strabismus. Even in Graefe's time it was the opinion of Donders that it is not the muscle that is at fault, except in paralysis, but fixed conditions of the eyeball, to which may be added, in exceptional cases, central disease.

In the interests then, of what I conceive to be scientific truth, I object to the use of the term, "monolateral strabismus," excepting as referring to the affection resulting from paralysis, as indicated above. While there may be an apparent monocular convergence or divergence of one eye in functional strabismus, it is always shown to be bilateral on the application of a simple test.

HYDROPHOBIA AND THE PASTEUR METHOD—A REJOINDER.

By CHARLES WINSLOW DULLES, M.D.,
PHILADELPHIA.

LECTURER ON THE HISTORY OF MEDICINE, UNIVERSITY OF PENNSYLVANIA; FELLOW OF THE COLLEGE OF PHYSICIANS; AND FELLOW OF THE ACADEMY OF SURGERY OF PHILADELPHIA.

The Medical Record of November 23, 1901, contains an article criticising one of mine in the same journal of July 13. Parts of this criticism are marked with so much acrimony that I am constrained to say that after twenty years' work on the subject of hydrophobia any reply to accusations of foolishness and dishonesty is either needless or useless. The principal counts of the scientific part of the criticism, as I understand them, are:

1. That I deny that rabies is a specific disease.

2. That I deny that the muzzling of dogs is a preventive of hydrophobia.

3. That I err in asserting that the muzzling laws of England are as inefficient as they are in this country.

4. That in tabulating the statistics of Paris I misplaced the record of a year in the interest of my argument.

5. That I err in asserting that hydrophobia may follow the bite of a non-rabid dog.

6. That I have slandered Pasteur.

These points I will consider seriatim.

1. In respect to the assertion that I deny that rabies is a specific disease, I will say that it is an error of fact, or an inaccurate expression. In the article criticised, just after the "Table of Situation of Bites, et cetera," I have defined my view so plainly that I need not repeat it, and it surprises me very much to find a disputant with this clear explanation before his eyes attributing to me any such assertion as that "rabies" is not a specific disease. Everything depends upon definitions in such discussions. Twenty years ago a number of different things passed for rabies in dogs, and the diagnosis was founded upon clinical symptoms and appearances discovered in autopsies upon animals, the various and inconsistent characters of which are known to every one who is acquainted with the work and writings of Delabere Blaine, Youatt, Hertwig, Bruckmüller, Bollinger, Fleming, G. Colin, Bouley, Decroix, Lorinser, Galtier, Signol, and other authorities in the department of veterinary medicine. But since Pasteur came upon the stage most writers on the diseases of animals have agreed to call by the name of rabies that condition alone which is distinguished by the fact that material derived from portions of the nervous system of an animal presenting symptoms of rabies when inoculated in a specified manner upon a second animal will produce a certain series of symptoms, while material derived from this animal in turn is capable of producing a like condition in a third, and so on in series. Now, there can be no question that it is proper for students in a particular department of science to agree upon a definition, and after that those who wish to be understood in discussion must accept such definitions—at least *pro hac vice*. This is the present state of affairs in regard to the question: Is rabies a specific disease? The definition is, I think, weakened by the fact—seemingly unknown to many writers—that these conditions have been fully and completely met by a variety of materials derived from the animal and even from the vegetable kingdom, having no connection whatever with the disease in animals called rabies, as has been described, for example, in the Bulletin of the Department of Agriculture in the United States, and in the Bulletin of the Academy of Medicine of Paris, and elsewhere.

2. In regard to the statement that I deny that muzzling of dogs is a preventive of hydrophobia, I may also say that this is an error; for I explicitly say in the next to last paragraph of my article of July 13 that I favor the application of precisely this measure.

3. My critic characterizes as a "most glaring misstatement" my assertion that the muzzling laws of England are as inefficient as they are in this country. I am not surprised that one who could fail to understand me in the two points already mentioned should go astray in consequence of an expression which, I admit, would have been less vulnerable if more exact. What I meant, and what I mean is, that the muzzling laws in England have been and are—as the muzzling laws in this country have been and are—inefficient. I am acquainted with all the figures cited by my critic to indicate the opposite—and with many more, gathered not only from government records of Great Britain, but also from medical journals and other publications; and I find in them all, and especially in those he cites, such evidences of irregularity and inconsistency, and such warrant for contradictory inferences that I do not wonder at the opinion expressed by two of the most distinguished and capable British students of rabies and hydrophobia—Dr. Thomas M. Dolan and Sir George Fleming—that "to be beneficial it is obvious that the employment of the muzzle must be universal." This expression is stronger than any I have used, and it indicates how the greatest veterinary teacher England has ever known re-

garded such imperfect, unnecessary, and spasmodic applications of a muzzling law as is implied by the followers of Pasteur with accounting for the difference in figures for hydrophobia in England and in Germany as compared with France. Furthermore, the figures given in my previous article are fortunately conclusive as to the fact that the use of the muzzle cannot be looked upon as the only or chief reason why on one side of the Rhine—across which it is said that dogs can find their way—the cases of hydrophobia, according to the Pasteur Institute claims, should be numbered by thousands and on the other side by units; and one who holds with any honest faith in this matter might well reflect upon the inferences to be drawn from the conditions found in Constantinople and many Oriental towns, in which, though they are thronged with vagabond dogs, hydrophobia is so nearly unknown that distinguished authors have asserted that it never occurs there. Now with these points clearly made, I will add to what I stated in my previous article that a careful study of the conditions under which hydrophobia (I am not talking about rabies) occurs in countries well supplied with hydrophobia rations—and especially with Pasteur institutes—leads me to believe that in them it is better for mankind that dogs roaming at large should be subjected to the inconvenience of a properly constructed muzzle than that human beings should run the risk connected with dog-bites irrespective of the hypothesis of a specific virus—this view being founded upon the psychical effect of bites in civilized countries. To further elucidate the consistency of this opinion with that expressed above would be to impugn the intelligence of my readers.

4. The fourth point made by my critic is that, in tabulating the statistics of hydrophobia in Paris furnished by Dujardin-Beaumetz, I put 1885 with the years of the vogue of the Pasteur methods, which I am sorry to find he characterizes as a "deception," asserting himself that "the Pasteur treatment did not begin until November 1, 1885." For the few readers of the MEDICAL RECORD who do not know the facts already, I will state that the method referred to was first employed by Pasteur on the boy Joseph Meister—not on November 1 but on July 6, 1885, at 8 P.M.; that his report of the experiment was made to the Academy of Medicine on October 27; and that long before that date the daily papers of Paris had been exploiting his experiments in connection with this subject. In my article of July 13 I alluded to Pasteur's boasts in the Paris *Figaro*, and especially to one in that daily paper of May 10, 1884—a year and a half before November 1, 1885—which was cabled around the world: "From to-day anybody bitten by a mad dog has only to present himself at the laboratory of the École Normale and by inoculation I will make him completely insusceptible to the effects of hydrophobia even if bitten subsequently by any number of mad dogs." I will not weary my readers by refreshing their memories in regard to the way in which the French mind was inflamed on the subject of hydrophobia during a large part of the years of 1884 and 1885, except by reminding them of the fact that the daily journals of France, using material furnished by Pasteur, played in this a much more important rôle than the communications made by Pasteur to the Academy of Sciences or the Academy of Medicine.

I will not involve those whom I am now addressing in a new discussion of statistics; for I am quite willing to abide by an intelligent study of those I published in my previous article as compared with those contained in the article of my critic. It will be noted that I then cited figures furnished by followers of Pasteur as being unlikely to be questioned by his other followers, and by my own statistics, which I have gathered, not by a study of newspaper clippings—as is intimated by my recent critic and has been previously intimated by a veterinarian of this city—but by extensive correspondence and through investigation and analyses of facts accumulated during a period now covering twenty years. It were a waste of time to dispute long with anyone who, having access to the literature of this subject, could intimate that my methods of study have been childish, or would overlook the carefully prepared data I have presented in my many publications, while he accepts without question *ex cathedra* assertions of Pasteur in regard to matters about which he was utterly ignorant, as honest critics in his own country have repeatedly, and some not unkindly, pointed out.

5. The next criticism that I wish to comment upon is that which treats as "absurd on the face of it" the idea that the congeries of symptoms often called hydrophobia is about as likely to follow the bite of a dog that is not rabid as the bite of one that is. My critic does not quote me exactly in this respect, and I need only invite any intelligent person to consider carefully what I said on the subject in my article of July 13, 1901, adding, for those who attach great importance to the opinions of veterinarians, a reference to the conversion of that great English veterinarian, Sir George Fleming, to the opinion that hydrophobia may be acquired from the bite of a dog not rabid, as fully explained in the *Veterinary Review*, and in the *Lancet*, London, March 4, 1876, page 359, where the cases reported by Fleming are spoken of as having "All the definiteness of a designed experiment," and to the records by careful writers, too numerous to mention here, of hydrophobia followed by death from bites of perfectly healthy animals, many of which survived their victims.

6. As to the charge that I have "slandered" Pasteur, I do not wish to elaborate much the ideas I hold as to the worthlessness of the Pasteur method for treating hydrophobia, but even at the risk of bringing upon my head further vigorous expressions of personal condemnation, I cannot refrain from recalling, to those who have not had time or inclination to follow this subject unremittingly and to every quarter of the globe, the fact that no believer in these methods can adduce a single country in which, taking a series of years, anything can be shown to indicate that it has lessened the actual number of deaths from this singular disorder, and it is a very impressive fact that in places like New York, Chicago, Baltimore and (recently) Pittsburg, no sooner has a Pasteur Institute been established than claims are put forth which imply that suddenly the danger of death—as indicated by the claims of rescues performed by these imitators of their great prototype—has risen to unprecedented figures. My recent critic asserts that, in my opinion of the Pasteur methods, I am out of harmony with the great body of my profession. Well, the reproach of being out of harmony with the majority has been endured before in the history of the world, and so long as the regions where the views I hold prevail furnish a relatively small number of cases of so-called hydrophobia, some comfort may be drawn from a comparison of this happy coincidence with what takes place around the infectious foci of Pasteur Institutes. That an opportunity for administering the Pasteur method should have been recently furnished in Berlin does not indicate that there is any exceptional number of unwise persons in Prussia. What in-

fluence such an opportunity will have in a country where the *Kaiserliches Gesundheitsamt* reported in six years (1889-1894) 2,713 rabid dogs that died or were killed, and 8,862 killed by the police, and in addition 1,639 vagrant and suspected dogs that were killed, with only ten deaths from hydrophobia, the future will show; but it is to be hoped that it will not be like what so elates the Pasteur followers in France and Hungary and Italy and even America! The latest information in regard to the customary result of establishing a Pasteur institute comes to me in the last bulletin of the Mexican National Board of Health, which reports that since the Pasteur treatment was introduced there in 1885 four thousand persons have been treated, of whom three have died. Think of the possibility of thousands of cases of hydrophobia in Mexico in that time!

As to the expressions: "slander" and "villification of Pasteur," and so on, I would remark that there is accessible to everybody within reach of a respectable medical library a carefully prepared article that I published in the MEDICAL RECORD, February 13, 1886, in which I went over in detail the steps of Pasteur in establishing a method for the treatment of hydrophobia, and in this I set forth the singular inconsistencies and irreconcilable differences in his various communications on the subject; but I also duly recognized the merit of his real scientific work, regretting that his essays in the field of rabies and hydrophobia should be so undeserving of a place with it. None of this I need repeat now; but I may add to it a reference of my readers at this time to the numerous instances in which honest men in France have lamented the scientific absurdities and the practical defects of Pasteur's work in the preparation of his most exploited preventives. I happen to have before me the scientific criticism of Frisch of Vienna, in regard to his experimental work; the expressed disapproval of Mauriac of Bordeaux that Pasteur should have founded his notions upon the erroneous figures supplied him by Leblanc, which exaggerate the hydrophobia mortality enormously; the exposure before the Society of Medicine and Surgery of Bordeaux of the nearly doubling of the figures representing the number of persons treated in the Pasteur Institute from the Department of Gironde, in which Bordeaux is situated; the systematic correction by Duluc of Bordeaux of other figures upon which the Pasteur claims rest with his expression of pain and amazement that, in October, 1884, Pasteur should have declined to give the Société Vétérinaire de la Gironde information which would enable it to make experiments in the preventive inoculations of dogs, and the lame excuse offered for this unscientific and inhumane attitude. No such complaint is a surprise to me; for I have followed the work of Pasteur contemporaneously since he began to meddle with the subject of hydrophobia, and I will now state without reserve that his doings and his sayings have impressed me repeatedly as unworthy of a candid and humane scientific man. Whatever may be his contributions to science and, indirectly, to the art of medicine—and they have been very great—in the field of hydrophobia he was an ignorant pretender. More than this, the methods he used to exploit and reserve to himself the material advantages of a mode of treatment which he repeatedly changed after declaring it "perfect" and "infallible," were those of a charlatan, for example his announcement to the New York *Herald*, January 1, 1886, that "no one in the world outside of M. Pasteur and his laboratory was capable of undertaking the treatment safely," and that "a hospital in Paris would suffice for the whole world." For years he and his followers maintained a sort of propaganda, and the world was flooded through the secular journals in both hemispheres with claims and boasts that had and have no warrant whatever in fact. The emptiness of these claims can be seen by the published and undisputed lists, with names and addresses and dates, of persons who have died of presumable hydrophobia after treatment in Pasteur institutes and from the actual statistics of hydrophobia all over the world before and since the Pasteur era. Still—as before—we find that persons, like the inhabitants of Constantinople, most exposed to the bites of vagrant and vicious dogs seem to enjoy a peculiar immunity against the consequences proclaimed by the followers of Pasteur, of which a striking illustration was furnished in England, where in its first zeal the famous "Royal English Hydrophobia Commission" estimated that preventive treatment would be required for 860 persons annually in England alone!

In contrast to this foolish, Pasteur-influenced estimate of the liability of the English to this disorder, I would cite an ante-Pasteur statement of Mr. Scoborio, Manager of the London Home for Lost Dogs, that 200,000 animals had been brought to their kennels, 95,000 of which had been taken up by hand by the police; yet, notwithstanding the frequency of severe bites, hydrophobia had "never occurred among Metropolitan police, as shown by the medical returns," adding, "at the Home, where a stream of 15,000 dogs per month passes through the premises, bites are a daily occurrence, yet not once during the last seventeen years has hydrophobia resulted from such injuries."

My whole attitude to this subject of hydrophobia and the Pasteur methods will, perhaps, be better understood if I call attention again to the fact that I am not talking about "rabies" at all. That is a subject about which I have some information, but which I never discuss in public, because I have thought it wiser to restrict myself to that of hydrophobia in mankind. I do not find fault with the definitions of those who have made rabies a special study; but when it comes to hydrophobia I must endeavor to maintain the opinion I have formed from long and painstaking study and observation, that this disorder is not the result of the inoculation of a specific virus, but either a symptom occurring in some one of a variety of diseases or a psychical manifestation, and that the cases which can be fairly classed under the latter head have very often followed the bite of a perfectly healthy dog; and I believe that anything which attracts unusual attention to this subject—either public discussions or injuries that may seriously alarm a person bitten—favors the occurrence of cases presenting the symptoms of what is called hydrophobia. For this reason I regret the establishment of Pasteur institutes, and would consent that dogs should be subject to the inconvenience of muzzling, although I do not believe, considering it as a purely academic question, that this measure could otherwise be justified.

Finally, I would like to repeat a remark that I made in a discussion of this subject five years ago: "Controversy in scientific matters is not unlike football of these days—it may be hard without being rude, and those who engage in it must be willing to give and receive assaults that are necessary to a fair decision and the truest outcome of the contest. In it all, the argument must be clearly distinguished from the individuals engaged in it. I hope, as you do, for the discernment of the truth; and I respect all who have the same hope, however I may differ with them now as to the question at issue."

4101 WALNUT STREET.

CANCER OF THE PROSTATE COMPLICATED BY GENERAL FIBROID CHANGE OF THE URETHRA—URETHROTOMY—PROSTATOTOMY BY THE BOTTINI METHOD—SUBSEQUENT PARTIAL ENUCLEATION.*

BY GRANVILLE MacGOWAN, M.D.,
LOS ANGELES, CAL.,
PROFESSOR OF GENITO-URINARY SURGERY IN THE UNIVERSITY OF CALIFORNIA.

A. B. M., seventy-six years of age, a farmer and stockman, came to me on November 1, 1900. For three years he has had great trouble in passing urine, and nearly all of the time has been obliged to use a catheter once or twice a day. His bladder is capacious. The largest catheter he has passed for a long time is No. 6, English, and this with a stylet.

Examination of the urethra shows dense organized stricture tissue, which extends from the meatus to the membranous urethra, and only admits a No. 9 French silk catheter, with the aid of a stylet.

Examination of the prostate, through the rectum, shows it to be a large nodular one. Some of these nodules are movable, others are dense and immovable. The prostatic enlargement extends upon each side far out along the pelvic bones. In the center the bladder may be palpated; there is no induration at its base. There is enlargement of some of the pelvic lymphatic glands.

Recently the patient has had complete retention, and has been often forced to pass the catheter every twenty minutes. Previously he had residual urine to the amount of about ten ounces. The urine is alkaline, very purulent, and has a fecal odor.

The urethral obstruction became so great that he could not, when he came to me, catheterize himself at all.

I sent him to the California Hospital, put in a No. 9 French silk catheter, and allowed it to remain until November 7, washing out the bladder daily, as thoroughly as possible, through this small tube. The drainage was not continuous, the end of the catheter being stopped with a small cork, which was removed when the patient desired to urinate. Urotropin was given internally, in a daily dose of 1.5 gm. On November 8 the urine had become clear and acid.

A No. 14 French silk catheter was introduced and tied in, the stricture having dilated enough, meanwhile, for this to pass quite easily. The patient had not been passing enough urine, so he was given digitalis with corn silk, in addition to the urotropin.

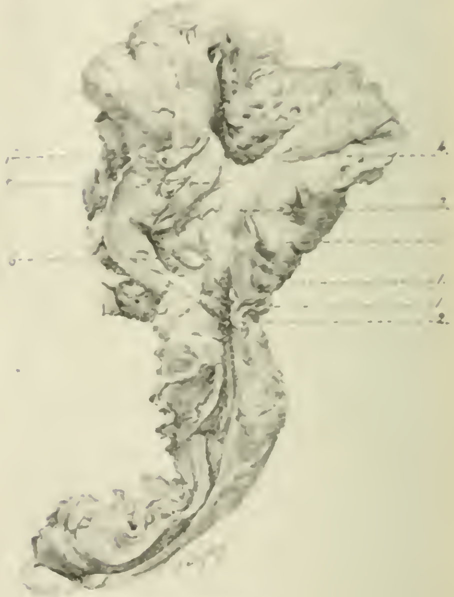
On November 14 a No. 16 F. could be passed easily, so the patient was allowed to catheterize himself until the 20th, when the very hard anterior stricture, which extended from the meatus to a point an inch posterior to it, was cut freely under cocaine, and the catheter replaced and tied in until the 22d, when it was removed, and the meatus dilated daily, until the 28th. The deeper strictures were then operated upon by the Fort method of electrolysis, using the 26 F. MacGowan electrolytic blade, after which a No. 17 soft rubber could be passed to the membranous urethra easily. But in order to enter the bladder, it required the assistance of a stylet, for there was great resistance to its passage in the deeper parts.

On December 7 I used a large MacGowan electrolytic blade, 32 F., hoping to overcome the obstacle in the deeper urethra. Several attempts were made at intervals of three or four days, in sittings of one-half to three-quarters of an hour, but without success.

This impediment appeared to be anterior to the prostate, and it was believed that if it were severed and dilated until healed it would be possible for the man to lead a comfortable catheter life, or for me to do a Bottini on him, for he decidedly objected to a prostatectomy.

On December 18 I did a combined internal and external urethrotomy. The hemorrhage from the former was so great that the latter was done as a safeguard, and advantage was taken of it to explore the membranous and prostatic urethra.

The prostatic enlargement was found to have encroached upon two-thirds of the membranous urethra, where a growth upon the left side, about the size and shape of a pecan nut, and roughly nodular, blocked the lumen of the canal. It felt as if it could be easily shelled out, and I was tempted to get rid of it in this way.



SCHEME.

No. 1. Cancer nodules.
No. 2. Membranous urethra.
No. 3. Urethral channel.
No. 4. D[illegible] bladder [illegible] prostatic p[illegible].
No. 5. Head of groove made by Bottini cautery.
No. 6. Depression from removal of [illegible] right lobe.

However, I suspected, from its appearance and feel, and from the results of the examination per rectum, that it might be cancerous. I had promised the old man not to do a prostatectomy on him, and, as the Bottini instrument was at hand, I was desirous of seeing what effect, if any, this operation would have in removing, or causing the atrophy of, such an obstruction.

Examination of the urethra nearer the bladder, and of the bladder neck, showed that there was, in addition, enlargement and obstructive growth of the prostate, intra-urethral and intravesical, posteriorly, and also upon the left side.

Two incisions were made with the Bottini, one posterior 4½ cm. long, and one 5 cm. long on the left side, through the impeding growths, the eye being used as a guide to the burning in the membranous urethra. There was more hemorrhage than I had ever seen following similar operations.

The perineal wound was packed, and a No. 22 drainage tube inserted into the bladder through the urethra. At midnight there was a free hemorrhage from the urethrotomy wound, filling the bladder with clots, which necessitated introducing a No. 40 perineal drainage tube, and the fastening of a No. 24 in the anterior urethra. The drainage tubes were removed on the fifth day.

---

* Read before the Los Angeles County Medical Society, July, 1901.

The patient had some elevation of temperature while the packing was in place, and some sloughs from the Bottini burn came away about January 1, being accompanied by drenching night sweats, and by a bad odor to the discharges. The night sweats were controlled by atropia, the odor by a return to the use of urotropin, which had been stopped for a time, and strychnine, suprarenal extract, and digitalis used *pro renata* as cardiac and renal stimulants.

On January 3 he voided about four ounces of urine, and on the 5th about eight ounces. I encouraged him to make every effort to pass his urine by allowing the bladder to get quite full. The catheter was used several times a day through the perineal wound. The anterior urethra, being dilated by a No. 28 steel sound, healed nicely, with the full caliber.

On January 9 an inflammation of the left epididymis occurred, and was quite painful and troublesome for two weeks. This was simply a recurrent trouble from which he had suffered, at intervals, for several years.

On January 19 he passed about five ounces of urine. He had been up and about every day from the 1st of January. On the 28th and 29th he voided two or three ounces of urine several times.

The perineal wound was now healed, and it was evident that the Bottini operation had not been successful in removing the prostatic obstruction. The brave old fellow requested me to try again, and gave me permission to do whatever I saw fit for the restoration of the ability to empty his bladder voluntarily.

On February 4 I reopened the perineum, and again examined the obstruction on the left side of the membranous urethra. It was divided into two lobes by the Bottini incision, and was considerably shrunken, but was still so large that there was no possibility of burning it in such a manner as to effectively remove its pressure upon the urethra, therefore I enucleated it.

What appeared, upon the surface, to be quite a small mass, proved, when I got through the capsule, to be much larger, very adherent, and difficult to enucleate. The easiest parts to peel out were those through which the Bottini had passed.

It was not deemed wise to shell out the remaining obstructing portions of the prostate, for the part removed seemed to be cancerous.

My finger detected quite a good-sized channel through the obstruction at the neck of the bladder. It was thought best to enlarge this with the electrocautery, believing that, when the slough came away, enough of the impediment would be removed to permit of his urinating through the channel, which was now clear from the meatus to the neck of the bladder. So three grooves, two upon the base, beside each other, and one upon the left, were slowly burned.

The large perineal drainage tube was inserted into the bladder again.

On February 12 it was noticed that fecal matter came through the perineal wound. I found a small opening well to the left of the median line, about three inches up the rectum, communicating with the space from which the prostatic nodule had been shelled.

This was closed, on February 13, by dissecting up the rectum and its muscular structures from the surrounding tissues, and pulling it down until the fistula was visible. Lembert sutures of Florentine were passed from without inward, and tied within the lumen of the gut, the ends being left long, plaited together, and allowed to protrude from the anus. The gut was then returned to its bed, and held in place by terraced catgut sutures and a circular row of sutures of Florentine. The surface of the wound toward the urethra was also terraced in a similar manner.

Experience has taught me not to be cowardly with old men upon whom it is necessary to do surgical operations about the kidneys and bladder, for, with skill, cleanliness, and careful attention to maintain the functional activity of these organs, severe operations are accompanied with but little more risk than they are on younger men. I never had anyone to operate upon with much less promise of success than this old chap.

His recuperative powers seemed perfectly wonderful, for he was uræmic and very weak when he came to me, but his rectal wounds healed perfectly, the fistula healed tightly, his kidneys acted very well, the slough passed off from the Bottini burn at the neck of the bladder, and this granular surface also healed.

He passed water naturally, in full flow, on March 3, but he died on the 9th, from recurrent secondary hemorrhage, which came from the cavity in the prostate from which the cancerous nodule had been dug out.

The first hemorrhage was noticed during the night of March 2. It was slight, flowed into the bladder, and stained the urine. On the morning of March 3 another hemorrhage packed the bladder with clots.

These were pumped out by a Chismore aspirator, and three ounces of aqueous solution of suprarenal extract left in the bladder, as it was supposed that the hemorrhage came from the Bottini wound. The patient was also given suprarenal extract, 5 gr. every two hours, for twenty-four hours.

This controlled the hemorrhage, but it recurred on the morning of the 5th. He became markedly uræmic, and died, after a severe chill, with a rise of temperature to 105°, on the morning of March 9.

Examination of the bladder and the prostatomembranous urethra shows, first, the presence of cancer nodules widely disseminated; second, a large, smooth, roomy groove through the obstructions of the urethra left by the healing of the channels on the posterior and left side of the vesical neck. This groove is lined with scar tissue, which is smooth, thin, and so perfectly flexible, that if I did not point out to you the spot burned, I think none of you would be able to select it as a scar following a burn. Third, my experience with this patient, also with another man with cancer of the prostate—who lived for several months after I did a Bottini prostatotomy upon him, with marked benefit—and a third patient, now living, who has prostatic cancer that may be observed with the cystoscope—who suffered with complete retention and difficult catheterization for nearly a year, yet who voluntarily empties his bladder completely and comfortably up to the present, since I did a Bottini upon him last March—leads me to believe that this form of operation is a feasible one, and to be recommended for trial by others in cancerous prostatic obstructions of the bladder neck, but of no use, for obvious reasons, if the obstruction is far forward in the membranous or prostatic urethra.

540 Douglas Block.

GONORRHŒAL RHEUMATISM

BY J. DOUGLAS WESTERVELT, M.D.,

SHREVEPORT, LA.

The etiology of this disease has, for many years, given rise to much discussion without adding any reliable information on the subject under investigation.

The disease is recognized by many able writers as a toxæmic effect of the gonococcus upon the general system, either by its presence in the circulation or by that of the toxins of this microorganism. They maintain that the specific urethritis is the local manifestation of the microorganism, and the accompanying arthritis is a localized product of a general infection. They go as far as to claim that the synovitis is in no way related to rheumatism, and even discard the name under which the disease is generally known, calling it gonorrhœal arthritis instead of gonorrhœal rheumatism. The reason set forth for such views is that the articular inflammation concurring with gonorrhœal urethritis is different from that of ordinary rheumatism. These writers seem to ignore, what is universally conceded, that the clinical features of a mixed disease are entirely different from the typical features of the diseases forming the complication. The fact that an articular inflammation associated with gonorrhœa is dissimilar to an ordinary synovitis furnishes no grounds for believing that these conditions have no inter-relation. It is claimed by these authorities that gonorrhœal urethritis causes the articular disease, and yet they cannot explain its mode of action in producing the two forms of inflammation. If the pyæmic theory is accepted, why are the joints alone involved? Why are not other tissues invaded? Why is the arthritis sometimes non-articular and sometimes polyarticular? Why should the large joints be more liable to invasion than the small joints, and why is the knee-joint so much more frequently involved than others?

A general pyæmic infection should not be so restricted in its operations. It is claimed, in behalf of the pyæmic theory, that gonorrhœal arthritis does not require for its production the usual exciting causes which invite rheumatic attacks, but can anyone name any special exciting causes which invariably give rise to an attack of rheumatism? Gonorrhœal rheumatism occurs most frequently in the early part of middle life; so does rheumatism. It occurs more frequently in males than in females; this is also the case with rheumatism. Gonorrhœal rheumatism occurs only in about 2 per cent. of gonorrhœal cases. If the gonococci, or their toxins, provoke the articular inflammation, it seems strange that they do so in only one or two cases in a hundred of gonorrhœal urethritis. According to the testimony of many trustworthy observers, the same forms of articular inflammation have been known to accompany urethritis not produced by the gonococcus. This weakens the theory of pyæmic infection, and strengthens the contention by many writers of concurrent rheumatic disease, as a dominating factor.

Furthermore, it is very rare to find pyæmia or septicæmia resulting from inflammation of mucous membranes, and if it should, other contiguous structures would be likely to suffer as well as the joints.

Is it possible that gonorrhœal pyæmia will produce gonorrhœal rheumatism and, at the same time, never cause pyæmic disease in any neighboring tissues or organs? It is true that the pyæmic theory is now more generally accepted than any other, but the clinical evidence upon which it rests will not bear a critical examination. It would seem, in the absence of any positive evidence to support the theory of pyæmia, that accidental rheumatism as an intercurrent complication would be a logical inference in the determination of factors in gonorrhœal arthritis. There is much more evidence in favor of this theory than that of pyæmia, but the tendency of most writers to reason from the standpoint of an unwarrantable bias leads them to ignore every argument which refutes the theory of gonorrhœal inflammation. They claim that the gonococcus has been found in these inflammatory lesions, but they overlook the fact that, in the majority of cases, it has not been found, and furthermore its presence does not prove that it causes the lesion.

The writer does not claim that all cases of arthritis in gonorrhœal disease are rheumatic, nor that the gonococcus never exerts any provocative influence over the arthritic inflammation. The main contention of this paper is, that the variegated clinical history of rheumatism shows that it is a potent factor in many localized lesions, and there is no justification in a sweeping denial of its relationship to gonorrhœal arthritis.

The symptoms of gonorrhœal rheumatism, during the course of gonorrhœal arthritis, are a sense of uneasiness, aching, stiffness, or lancinating pain in one or several of the joints. The knee is oftener involved than any other articulation, especially the left knee. Other joints may become consecutively or simultaneously involved. The articular inflammation usually develops in the later stages of gonorrhœa, and often after the urethral discharge has almost entirely ceased. The articular symptoms arise gradually, without any alteration in the external appearance of the joint. As long as the affected part is at rest, there is not apt to be much pain, but the least movement provokes it at once. The inflammatory process is of a subacute type, and it never announces its advent with a chill, as generally happens in pyæmic attacks. When the inflammatory attack reaches its culminating point, the joint may become distended, and give rise to considerable effusion. The articular inflammation may run an indefinite course, and last weeks or months. In these cases, if the effusion is of a fibrinous character, anchylosis may result. In the treatment of this disease we must not lose sight of the fact that we have to deal with a mixed form of disease. We have the gonorrhœal element confronting us, and we also, probably, have a rheumatic element to claim our attention. Besides these conditions, we may also be required to treat the general health of the patient. If there is a urethral discharge, it must be treated. If there is a rheumatic condition, it must be treated. If there is an impaired state of the health, this, also, must engage our attention.

The local treatment of the articular inflammation will not differ materially from that of any inflammation of the joints. We must allay inflammation, stimulate absorption of effusions, and restore normal functions of the articulation. There are many methods of accomplishing these objects. For the urethritis we may resort to installations of permanganate of potash, with the internal administration of codliver oil, with five grains of iodide of potassium to each tablespoonful of this preparation. A tablespoonful to be given four times a day, after meals and at bedtime. The iodide of potassium may be increased or diminished according to the requirements of the particular case. This disease, with its painful accompaniments, has a depressing effect on the vital processes, and rapidly impairs nutrition. The iodide of potassium, by its eliminating properties, removes the cause of the pains, and the cordial of codliver oil compound improves nutrition, tones up the nervous system, and, by regulating the kidneys, allays the acridity of the urine. With such a constitutional corrective, and suitable diet, and mild antiseptic injections or irrigations, this disease is readily subdued. Besides the general restorative action of the above remedy, it directly increases the excretion of urine and uric acid, and renders the urine less irritating to the inflamed mucous membrane of the urethra. This preparation is, therefore, intended to meet both the rheumatic and gonorrhœal conditions of this troublesome disease.

It is palatable and efficient in the doses named. A tablespoonful after each meal and at bedtime being the average quantity required for successful results.

Folliculitis (Acne) Exulcerans Serpiginosa Nasi (Kaposi).—E. Finger reviews the literature relating to the five cases of this rare cutaneous affection which have hitherto been reported and adds the observation of another case. The first manifestation was a small papule, which appeared on the tip of the nose and rapidly ulcerated, apparently as the result of scratching. It was regarded as syphilitic in nature and for three months was treated accordingly. Such treatment, however, was without avail and the lesion increased rapidly in extent. When Finger first saw the patient the ulceration completely surrounded the right nasal orifice and involved the corresponding alaqual nasi and the contiguous portions of the septum and upper lip; the mucous membrane of the right nares, to a distance of about one c.m. from its orifice, was also involved. The ulcerated area was surrounded by an inflammatory zone, and was covered by a yellowish thick exudate, under which course granulations were seen. An ordinary acne eruption, with numerous comedones was more or less abundant upon the face, chest and back. Local treatment only was used. This consisted of 2 per cent. boro-vaseline. Examination at the end of three weeks showed that the ulcerated area was gradually healing from without inward, but that on the neighboring sound skin several new papules had appeared, which gave evidence of beginning ulceration. Five per cent. boro-vaseline was ordered, and, in addition, the ulcerated surfaces painted daily with a 2 per cent. solution of carbolic acid. In one month from this time all the lesions had entirely disappeared, the ulcerated surfaces being replaced by cicatricial tissue. A microscopical examination showed that the process was simply inflammatory in nature and follicular in origin. No giant cells were found. Bacteriological examination showed the presence of numerous microorganisms, especially staphylococci. No tubercular bacilli were found. This case increases the evidence which goes to show that occasionally there occur serpiginous ulcerative cutaneous lesions of follicular origin, which are neither syphilitic nor tubercular in character.—*Wiener klinische Wochenschrift*, March 6, 1902.

On the Mode of Action of Narcotics.—C. R. Marshall says that if the anæsthetic action of a substance is dependent upon its solubility in fat-like compounds, then we may formulate the following theses: (1) All chemical, for the most part indifferent substances, which are soluble in fat and fat-like bodies, must be narcotic to living protoplasm, in so far as they can diffuse into it; (2) The action must appear earliest, and be most powerful in those cells in the chemical composition of which these fat-like bodies preponderate and play an essential part in the function of the cells—mainly, therefore, in nerve cells. The relative strength of action of such narcotics must depend on their mechanical affinity to fat-like substances, on the one hand, and to the other components of the body, *i. e.* mainly water, on the other; therefore on its partition coefficient is a mixture of water and fat-like bodies. This theory does not explain the action of nitrous oxide, whose action is physical, not chemical, and which rapidly diffuses into the tissues. Owing to its slight partition coefficient in favor of oil, it tends to accumulate in "lipoid"—containing cells. Whether we shall ever succeed in getting to the bottom of sleep and narcotic action is still a matter of opinion, but, the author says, we must welcome every addition to the subject, and this theory of partition coefficients is assuredly one.—*The Medical Chronical.*

Ichthyol in Pulmonary Tuberculosis.—J. D. Astrachan reports favorable results obtained by the use of ichthyol in pulmonary tuberculosis. The therapeutic effect of this substance is due to the sulphur which it contains. When ichthyol is broken up in the intestinal canal, the sulphur set free forms new compounds, which possess a marked bactericidal action. The author has treated twenty-one cases of phthisis with ichthyol; of these two were in the first stage of the disease, ten had suffered with the disease for from four to five years, four from five to seven years and one for thirteen hours. Two were cases of "galloping" phthisis, and two were cases of chronic bronchitis with an existing hereditary tuberculosis. All of these cases were markedly improved except the two cases of acute phthisis, which were apparently not influenced by the treatment. Two of the cases were apparently cured. Very soon after beginning the administration of ichthyol the hæmoptysis, cough and night sweats diminish, the appetite and general condition commence to improve, and the patient begins to increase in weight. Ichthyol may be administered either in pill form, combined with magnesia, or in liquid form, dissolved in water and glycerin. The dose should not exceed 4.0 daily. It is best to begin with small doses and gradually increase until the maximum amount is taken. The daily quantity given should be divided into three doses, one of which should be taken after each meal. The author describes in detail three of the cases which were treated by him in the above manner.—*Allgemeine medicinische Central-Zeitung*, March 1 and 5, 1902.

A Case of Fusiform Dilatation of the Œsophagus without Intrinsic Stenosis.—George A. Peters reports this case of a farmer, aged thirty-five years. There was no history of cancer in the family. About five years previous to this observation the patient suffered from regurgitation of food. This was never sour. The eructation was not true vomiting. There was sometimes a troublesome hiccough, and there was evidently a spasmodic element in the case. Finally a gastrostomy was performed with gratifying results at first, but in about six months the patient became nervous and anxious for further intervention. The writer made a diagnosis of hour-glass contraction of the stomach. Operation showed this to be an error. The sac, which received whatever was swallowed, was situated above the diaphragm. The patient died within eight hours from exhaustion and failure of circulation. Post-mortem examination showed that the stricture was extra-œsophageal and due to the tight clasping pressure of the pillars of the diaphragm. There was no sign whatever of intrinsic stricture. There was no scarring. The stricture was due to the hypertrophied condition of the pillars of the diaphragm, with or without a degree of spasm in this muscle.—*The Canada Lancet.*

An Unusual Case of Subperiosteal Hemorrhage of the Orbit Following an Uncomplicated Delivery.—Edgar S. Thomson describes this case. The patient was one week old when brought to the hospital. No instruments had been used in delivery. The day after birth the right eye began to protrude. This condition continued to grow worse till the lids could scarcely be closed. Palpation discovered an indistinct mass in the upper part of the orbit, back toward the apex. The orbital tissues were much swollen. Hot applications failed to reduce the swelling. The cornea became dry and deeply infiltrated. Two days after admission to the hospital the eye was [illegible] A large fluctuating mass was found near the end of the [illegible] near the [illegible]. As it was being [illegible] several [illegible] of blood [illegible] and serum [illegible]. No [illegible] could be [illegible]. The swelling rapidly subsided and three months after the operation, when last seen, [illegible] well and strong. There must have been some [illegible] during birth, which [illegible]. There was probably a [illegible] of the [illegible]. At the time the child was [illegible], and probably [illegible] considering the conditions at that time. —*Lancet*.

Wounds of the Heart.—L. L. Hill reports two cases, the first being that of a girl of eight years. She had carried in her shirt-waist a needle two and a half inches in length, which she had driven into her heart by accidentally falling against a tree. Her countenance was anxious, pulse rapid and weak, and respiration somewhat labored. She had severe pain about her heart. Upon inspection it was found that the foreign body had entered the fifth intercostal space on the left side, and with the pulsation of the heart the head of the needle could be seen to move under the skin. Under cocaine, an incision one inch in length was made down to the needle and the latter extracted. Recovery was without incident. The second case was that of a man aged twenty-eight years, who had received a stab wound in the fourth intercostal space a little to the right of the left nipple. Seen shortly after the injury there was complete relaxation of the extremities and the pulse was hardly perceptible. The countenance depicted a suffering and distress that would seem to welcome death with the wintery sterility of the grave as a kind and sympathizing friend. Auscultation revealed the heart sounds very indistinct and percussion elicited increased dulness. It was evident that the pericardium was rapidly filling with blood, and that the heart's action would soon be overcome by compression. The external hemorrhage was slight. The blood was evacuated by enlarging the opening in the pericardium, and the patient's condition at once improved and he ultimately recovered, though subsequently traumatic pericarditis supervened. —*Indian Medical Record*.

Intermittent Claudication.—William Osler describes this condition in the horse, and then reports the histories of two patients who suffered from the same affection. The first patient was admitted to the hospital with aneurysm of the abdominal aorta. There was also general arteriosclerosis. The sac was wired, and his condition was greatly improved. Some months later, when he returned for examination, he reported an additional symptom. After walking for a certain distance his legs would give out completely. After resting a few minutes he could go on again. There was no paralysis, and no cramps, but a sensation of dead, heavy weight in the legs. The quantity of blood which reached the legs was insufficient, causing relative ischæmia and inability to walk. In some cases there are cramps and tingling. The second patient had general arteriosclerosis. She had the first attack after eating a very hearty dinner. After walking a short distance she lost control of her legs. Warmth was applied to the legs and careful friction, and she did remarkably well. She was also put to bed, as rest is essential. There have been cases reported in nervous individuals in which the condition seems to depend upon vasomotor disturbances. —*The Montreal Medical Journal*.

The Newest Physiology of Digestion in Relation to Treatment.—Alfred W. Perry describes Pawlow's recent researches in digestion. One of the most striking results of these researches is the proof of the exactness with which the gastric and pancreatic secretions correspond in quantity and strength in the various digestive ferments, pepsin, trypsin, amylolytic and fat-splitting ferments, with the need for them in the various foods taken. In view of this fine adjustment of nature we cannot be too [illegible] of [illegible] it by [illegible] to help indigestion [illegible] the [illegible] not [illegible] the acids which naturally exist in the body or food for the digestive ferments. The most rational gastric therapeutics is to remove motor derangements by mechanical and hygienic methods, and deficiencies in any of the long series of digestive acts by attention to the quantity, quality, [illegible] temperature, times of taking and separation of the different classes of food from each other, separation of fish from meat, etc. The author gives details in the carrying out of these principles. —*Pacific Medical Journal*, March, [illegible].

A New Treatment for Plague.—In the treatment of septic plague R. Watson recommends much larger doses of lime than of the other remedies, and the same small doses of [illegible] for the first twenty hours to reduce temperature; lithia in five or ten grains, and if the brain is still affected, a dose or two of five or ten grains of alum. The lithia after twenty-four or thirty-six hours brings out a profuse sweat, which continues till convalescence is established. Since the uric acid, lithia and other treatments are depressant, lime should first be given to strengthen the heart and give stamina. The next drug that should be used is [illegible], and then the other drugs enumerated. Where a pulse is quick, without a corresponding high temperature, it means that the heart is giving way; then add brandy, digitalis and strychnia to the treatment. Where a pulse is very slow it also indicates cardiac danger. The pulse common in plague is evidence of uric acid in excess in the brain, is met best with large doses of tincture belladonnæ and lime. For "quick respiration" the writer recommends tincture cannabis indica [illegible] to ♏ xv., with tinctura ferri perchloride ♏ v-x. —*Indiana Medical Record*.

The Instrumental Relief of Acute Retention from Prostatic Enlargement.—W. T. Belfield offers the following conclusions: (1) Acute retention from prostatic enlargement is due to an œdema, not a rigid obstacle in the prostate; (2) This œdema can be passed sometimes by a Nélaton, always by a Mercier catheter; (3) A metallic catheter is curved to traverse the normal deep urethra, and is therefore not adapted to traverse the elongated distorted urethra of the enlarged prostate. Hence it should be used only as a last resort and then never forcibly. It is understood that urotropin or cystogen should be administered at once in all cases of acute retention, and continued until the danger of pus infection of the urinary tract has passed. —*Therapeutic Gazette*.

The Etiology of Acute Dysentery in the United States.—E. B. Vedder and C. W. Duval conclude from their researches, that (1) several standard cultures used in their study are indistinguishable—a conclusion previously reached and stated by Flexner; (2) the acute dysentery of the United States is due to a bacillus indistinguishable from that obtained in epidemics of dysentery in several other parts of the world; (3) the sporadic and the institutional outbreaks of acute dysentery are caused by the same microorganism, and this organism is identical with that causing epidemic acute dysentery; (4) the cause of acute dysentery, whether sporadic, institutional or epidemic, is *bacillus dysenteriæ*, Shiga. —*The Journal of Experimental Medicine*.

Surgical Operations on Old People.—J. C. Sexton believes that it is disease and not years that makes people old. He contends that the shock of operation, pure and simple, is not a great factor in the surgery of the aged. The shock of blood loss is, and there are many who do not think there is very often any other kind of shock. It does not appear to be necessary to produce deep narcosis in old people. The extreme sensibility of the nervous system incident to the prime of life seems dulled in old age. Old people can endure a great deal and have the same right to surgical skill as any one else. —*Indiana Medical Journal*.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 Fifth Avenue.

New York, May 3, 1902.

THE TREATMENT OF TROPICAL DYSENTERY.

Now that the United States has control over tropical lands, and that a large number of her citizens live in these parts, the climatic diseases cannot but possess peculiar interest for the medical profession.

Dysentery is one of the most prevalent maladies of the torrid zone, and is, at the present time, especially rife in the Philippines. The latest report of sickness received from those islands gives the following table of the most important diseases at the four main military hospitals: Dysentery, 16.7 per cent.; diarrhœa, 6.91 per cent.; typhoid fever, 0.33 per cent.; gastric disorders, 5.07 per cent.; tuberculosis, 1.24 per cent.; venereal diseases, 15.54 per cent.; insanity, 2.08 per cent. It will thus be seen that dysentery is the most fruitful cause of sickness among our troops in the Far East, and not only is this the case now, but at all times the affection prevails to a greater or less extent.

With regard to the treatment of dysentery, as with almost every disease, there is no specific remedy. Preventive measures carefully followed are the surest safeguards against contracting the complaint.

Great Britain, with her numerous and long-held tropical colonies, has had the best opportunities of studying diseases incidental to these portions of the globe.

Dr. Davidson, who lived in Mauritius for many years, writes as follows, in "Allbutt's System of Medicine on Dysentery":

"The resident in countries where the disease is endemic or epidemic, should see that the soil in the neighborhood of his dwelling is not subjected to fecal pollution. He should make sure of the purity of his water supply; and if there be the slightest reason for suspicion on this score, the water should always be boiled before use. Food should be of good quality, well cooked, and excess and defect alike avoided; alcoholic stimulants, if used at all, should be taken in strictest moderation. Diarrhœa and constipation alike should be guarded against as far as practicable. Exposure to cold and wet must be avoided. When the clothes get wet, they should be changed as soon as possible. An abdominal belt of flannel should be worn in the tropics. Dysenteric stools should be disinfected, and disposed of by covering them deeply with earth at a distance from the dwelling. In camps they should be disinfected immediately, and then disposed of by cremation."

There can be no cavilling at the foregoing rules for prevention, but with respect to the remedial and curative treatment of dysentery, authorities on the matter are, of course, not nearly so unanimous in their views.

The same kind of treatment will not benefit all forms of the disease, nor will one drug answer in all its stages. In uncomplicated cases of tropical dysentery, however, the British school of medical practitioners hold that ipecacuanha is the sheet anchor. This drug, in combination with salines, they claim, acts as a most efficient intestinal evacuant.

In the treatment of dysentery in war and famine, calomel has been the drug chiefly relied upon, but irrigation of the bowels with antiseptics has been most successfully practised in treating dysentery and allied conditions among the British troops in South Africa.

Dr. Henri Lafleur, McGill University, Montreal, writing on this point, says that irrigations of antiseptic solutions is the most rational and direct method of treatment. The amœba is susceptible to the action of solutions so dilute as to be only feebly toxic, and consequently gives us a stronger hope for the success of this method. Quinine, corrosive sublimate, nitrate of silver, nitric acid, and, latterly, permanganate of potash, are among the antiseptics which have been chiefly used for this purpose.

In the Paris letter to the *Therapeutic Gazette*, March 15, is an account of the treatment of tropical dysentery by Dr. Plehn, which reads as follows:

"Dr. Plehn, who has been practising a great many years in Africa, has published, recently, an interesting article in the *Deutsche medicinische Wochenschrift*, on the treatment of dysentery. This treatment is based on the successive use of purgatives, calomel, and subnitrate of bismuth. The most important part of the treatment is the method to be used in exhibiting successively these different drugs. As soon as there is a suspicion of dysentery, the bowels are flushed out; if the diagnosis is not quite sure, the inspection of the excreta shows if it is a true case of dysentery. If the case is one of dysentery, calomel should be given after twelve to eighteen hours. Twelve tablets should be given, each one containing about 0.03 centigram. . . . This treatment is continued three days, and then calomel is succeeded by subnitrate of bismuth. Tablets of fifty centigrams are given, twelve being given each day. This should be kept up three or four days, till the excreta becomes solid again, and do not contain any pathological products. As there is a tendency to constipation for the first few days, some mineral water should be given every day. Large enematas, containing a small amount of salicylic acid may also be used, but Dr. Plehn is not an ardent advocate of this treatment, which would seem to cause some weakening of the atony of the intestine."

In India dysentery is said to have been, and to be still, treated with good results by bael fruit. Naturally, judicious regimen is also a most important feature in the treatment of dysentery. Milk is recommended by the majority of authorities as the best staple diet, but if not found suitable, variations in food must be left to the discretion of the physician.

Careful supervision of sanitary arrangements is undoubtedly essential to prevent the occurrence of dysentery and especially is this so with European troops in tropical countries. With regard to treatment, it would seem that the use of antiseptics, either by the mouth or rectum, is, on the face of it, sound practice. The United States Army surgeons in the Philippines should be able to throw some fresh light on the treatment of dysentery generally, and on the drug treatment in particular.

All experts concur in stating that the only hope of cure for chronic dysentery, attacking Europeans living in tropical countries, is a change to more temperate climates.

THE ORIGIN OF CANCER

The Chelsea Clinical Society at its annual clinical debate, held on March 25, discussed the subject of cancer.

A communication sent to the meeting by Professor J. G. Adami of Montreal was one of the most valuable contributions to the discussion.

He said: "From a study of the syncytioma malignum, it might be legitimately deduced that there existed one form of tumor of highly malignant type in which the infiltrating cells were not those of the organism itself, but were derived from another organism. The infiltrative and invasive properties of these cells were not a new acquirement, but were an exaltation of properties normally possessed by them, or, more exactly, under normal conditions it was observed that there was an interaction of two forces—one the invasive properties of these cells and the other the protective properties of the surrounding maternal tissues, by which interaction the extent of invasion of the cells was strictly limited to the placental side. Dr. Adami's view was that the development of the syncytioma malignum must therefore be attributed to either an increase in the invasive properties of the syncytial cells or to a lessened resistance on the part of the maternal tissues, or a combination of the two. It was concluded, therefore, that if microparasites played any part in the production of the tumor that it must be either by exalting the infiltrative powers of the one, or by lowering the resistant powers of the other. Dr. Adami pointed out that proof positive of the existence of such specific microparasites was still wanting, and in its absence he found it difficult to conceive how specific microparasites could bring about those results. . . .

The prevalent conception of cancer parasites, as existing within the cancer cells, involved the idea of malignant growths being the product of parasites acting within parasites, because, as shown by the study of the syncytioma malignum, the tumor cells themselves were essentially parasitic in the organism.

In short, according to Dr. Adami, if the present popular idea was traced to its legitimate conclusion, the most that could be said for it was, as the association of parasitic ideas might already have occurred to some, that the theory was in harmony with the great generalization of the poet who wrote that

> Great fleas have little fleas upon their backs to bite them,
> And little fleas have lesser fleas, and so on ad infinitum.

Dr. Adami wished to know if that generalization was also to be applied to explain the action of pathogenic bacteria. In the long-continued action of microparasites he was willing to recognize a process which might, like other modes of stimulation, initiate aberrant and neoplastic cell growth, but beyond that point he contended that they seemed to be asked to contemplate a most extraordinary condition of affairs.

The parasitic theory of the origin of cancer presents to many earnest and keen investigators so large a number of difficulties that, before being accepted as the true cause, a quantity of unsolved points must be made clear.

The progress toward this end has of late been by no means rapid.

The increase, however, in the facilities for cancer research in various countries of the world gives rise to the hope that the final unravelling of its mysteries may not be far distant.

MOSQUITOS FROM THE LABORATORY POINT OF VIEW.

Since the investigations of Manson, Ross and the Italian scientists have shown that mosquitos are mainly responsible for malaria, and since Reed and others of the United States Army Medical Service have demonstrated a similar fact with regard to yellow fever, the literature concerning these insects has lacked in neither quality nor quantity.

Dr. William N. Berkeley of New York has, however, contrived to embody in a small space many of the salient points regarding the culicidæ and especially of the species Anopheles maculipennis and Stegomyia fasciata, viewed from the laboratory standpoint.

When it is borne in mind that F. V. Theobald, the well-known dipterologist of the British Museum, has recently published, in two volumes, an immense monograph of the Culicidæ of the world, but has announced that a third volume will be required to complete the subject, a clearer conception of the vastness of this field of research will be grasped than is usually the case.

Dr. Berkeley has summarized the most important conclusions already reached by investigators of various nationalities respecting mosquitos, besides which he has formulated some original views. His work* has been done at the Pediatrics Laboratory, at the laboratory of the Presbyterian Hospital, and at the Clinic of the Third Division of Bellevue Hospital. The book, which was issued from the Pediatrics Laboratory Press, is excellently illustrated by Miss Marion Salterlee and Dr. Louise Cordes.

The first five chapters of the volume are devoted to the Development and Mode of Life of the Culicidæ; Their Collection, Feeding and Breeding; Anatomy, North American (U. S.) Genera and Species, Dissection, Sectioning and Staining. The remaining four chapters, which treat of Mosquitos in Connection with Malaria, Filaria and Yellow Fever, are of exceptional interest to medical men.

Writing of the inoculation of mosquitos with malarial parasites, the author says: "By preference the mosquitos selected for experiment should be bred in the laboratory and should already have digested one meal of sterile blood. They should not be over a week old to insure their surviving the experimental bite as long as possible. If caught in the open, they should be kept long enough for possible previous infections to have disappeared as 'Coccidia' from the stomach-wall."

---

*Laboratory Work with Mosquitos. By William N. Berkeley, A.B., M.D., New York. New York: Pediatrics Laboratory, 1902.

In warm, summer weather mosquitos will not bite oftener than every two or three days—that is, as soon as the last previous meal has been digested. To make them bite well starvation for a day longer helps. Experiments of any real value should be conducted at a temperature of 80° F. (27° C), or over, and (as Giles has wisely remarked) preferably at that season of the year when the mosquito is normally most active. Large mosquitos, sucking more blood, are more liable to infection than smaller ones. Of a number of mosquitos biting a case of malaria at one time, as many as 25 per cent. may fail for some reason to "take." Allowing for deaths and accidents besides, it is usually not worth while to conduct an experiment with less than half a dozen insects to start with—twenty are a good number

Four or five separate cages of insects should be kept, each cageful to be fed on successive days, so as always to have a certain number of hungry ones on hand. The time of day taken for the bite should, if possible, conform to the feeding habits of the mosquito in question. Anopheles, however, though normally crepuscular in its feeding habits, will bite in the day-time. The soft part of the patient's forearm may be laid along the side of the cage. The insects will usually bite quickly through the wire gauze. Manson says that Anopheles puncture a moistened skin more readily.

The chapter on Mosquitos and Filaria briefly reviews the result of the investigations of Manson and others on the subject, and concludes by saying, "No human being has been, so far, experimentally inoculated, but the analogy to malarial disease seems perfect, and there is the strongest probability that the bite of a mosquito thus infected will engraft the Filaria into the human system.

The last chapter, dealing with Mosquitos and Yellow Fever, is by Dr. Aristides Agramonte, Professor of Bacteriology and Experimental Pathology, Medical School of the University of Havana.

Dr. Agramonte is inclined to disagree with the Englishman, Theobald, who states that but two species of Stegomyia fasciata and Stegomyia Signifera are to be found in the United States. Dr. Agramonte thinks that the species now known as Citæniorhynchus Wied presents many features analagous to them.

With regard to the habits of the yellow-fever-conveying mosquitos, many valuable points are given in the chapter, among which are the following: "They bite principally in the late afternoon, though they may be incited to take blood at any hour of the day. They are abundant in Havana from March to September, and, in the opinion of Dr. Agramonte, they are incapable of long flights unless very materially assisted by the wind. The Havana professor, referring to the length of time that infected mosquitos remain dangerous to the non-immune community, says that there is good presumptive evidence that the mosquito may harbor the parasite through the winter and be enabled to transmit in the spring an infection acquired in the fall. He also believes that yellow fever is restricted for its propagation to the genus Stegomyia.

Dr. Berkeley has succeeded in compiling a work which contains, in concise language and in clear phraseology, most of the important facts concerning the mosquitos about which he writes. His investigations are so valuable in their way, founded, as they are, for the most part, on purely original research, that they must needs give a new impetus to the studies of bacteriologists and clinicians in the lines indicated. Dr. Berkeley is well known to the readers of the MEDICAL RECORD by admirable articles on the subject contributed to its columns, and it is gratifying to note that the time, patience and thoroughness of his laboratory work have brought such abundant fruit.

The little volume will, undoubtedly, prove exceedingly useful as a handy textbook on the subject, and, as such, should have a wide circulation.

MARINE HOSPITAL SERVICE AND COMMUTATION OF QUARTERS.

Some comment has been excited in military and naval circles, outside of the medical departments of the army and navy, by a recent circular of the Treasury Department containing amendments to the regulations of the Marine Hospital service. The change relates to commissioned officers serving in the office of the Supervising Surgeon-General, giving them, in addition to their pay proper, an allowance as commutation of quarters, amounting to $80 per month in the case of an assistant surgeon, $85 per month in the case of passed assistant surgeons, and $90 per month in the case of surgeons. As the general commanding the army and the rear admirals of the navy only receive $72 per month for quarters, the surgeons-general of the army and navy, $60 per month, and the grades of major, captain and lieutenant (and their corresponding grades in the navy), $48, $36, and $24 respectively, the generosity proposed in the case of the Marine Hospital surgeons has provoked some invidious comparisons. That an assistant surgeon of the Marine Hospital service should receive an allowance for quarters three and one-third times greater than that granted assistant surgeons of the army and navy, and amounting to $8 per month more than that granted the lieutenant-general commanding the army, would seem, at first sight, to be more than unfair. It should not be forgotten, however, that the Marine Hospital service has no high grades with the much larger pay which medical officers of the army receive as colonels and lieutenant-colonels, and the medical officers of the navy receive as medical directors and medical inspectors, nor does the Marine Hospital service enjoy the benefits of the retired list, by which the future of officers of the army and navy are provided for. The increased allowances proposed, therefore, do not remove the deficiency under which the Marine Hospital corps, as a whole, labors. The whole incident serves as an excellent argument for putting all the medical departments of the Government services on an equal basis, as regards rank, promotion, pay, and allowances, and making the latter sufficiently generous to constantly attract to the Government services the best medical talent that the United States affords. The medical profession, by united action, has it in its power to do this, and to prevent the passage of unwise legislation affecting its representatives, such as that by which the efficiency of the Medical Department of the Army has been lately crippled. There is not a medical department under the Government which does not need—and is not worthy of—the support of the profession in the attainment of necessary reforms.

THE NEED OF PUBLIC BATHS.

The United States is behind most European countries, and lags far in the rear of Great Britain in regard to public bathing facilities.

New York City is a conspicuous case in point, for although some steps have been taken to provide the inhabitants of the poorer portions of the city with the means of ablution, yet, according to Mr. Charles Sprague Smith, Liverpool, with a population of 668,000, has spent on public baths more than all American cities combined, and Glasgow, with 732,000, has twelve public baths and five swimming pools.

The continent, and Germany in particular, is little behind England, while Tokio, Japan, with a population of slightly over 1,000,000, has 800 public baths.

The lack of public baths in an overcrowded city is naturally a menace to health. Even granting that the good effects of bathing are over-estimated, it is certainly a discredit to any city that a large proportion of its citizens should be compelled to go dirty, owing to the difficulties in the way of bathing.

John Wesley was wont to declare that cleanliness was next to godliness, and although, perhaps, the majority of persons will not go so far as the distinguished preacher in his belief in the efficacy in washing, yet it is, undoubtedly, a fact that bathing conduces both to health and self-respect.

An appropriation has recently been made in New York City for the erection of more public baths. It is to be hoped that those in charge of the arrangements for their construction will see fit to supply a sufficiency of shower baths. Dr. Simon Baruch has pointed out the general superiority of these to tub baths, and their adoption on a large scale is universal on the European continent.

Everywhere the city authorities have, up to the present, been niggardly in their expenditure for the physical and moral welfare of the people, but it would appear that with the incoming century a new era in municipal management may dawn.

SANATORIUM TREATMENT OF CONSUMPTIVES.

A report has just been issued of the results, so far, of the treatment at the hospital for tuberculosis, opened on Blackwell's Island on February 1.

The admissions have numbered altogether 273, of whom some were in a more or less advanced stage of tuberculosis, while others were suffering from the disease in primary form.

Of the 273 patients admitted fifty-five have been discharged, fifty as improved and five as hopeless. The first named patients have either returned to their work or, upon the advice of physicians, have gone to the mountains or to the country. Twenty-eight cases have been transferred to other wards for operation, or as exhibiting no symptoms of tuberculosis, and seventy-six have died. One hundred and fourteen patients remain in the hospital.

Of these, twenty are fresh cases as yet unclassified, forty are compelled to keep to their beds, and fifty-four are cases in the early stage. Of this latter number twenty-five have shown marked improvement, with an average gain in weight of 6.75 pounds. Eighteen have not progressed so favorably, but have made an average gain in weight of 1.9 pounds. Sixteen have retrogressed, and show an average loss in weight of 1.31 pounds.

On the whole, the experiment at Blackwell's Island has proved an almost unqualified success, and a useful object lesson on the need of extending this mode of treating consumptives.

The Practitioner (April), one of the most progressive of British Medical journals urges, in strong language, the adoption of stringent precautions to check the spread of pulmonary tuberculosis, and draws attention to Dr. Osler's remarks before a joint meeting of the Maryland Public Health Association, the Medical and Chirurgical Faculty and the Laennec Society. Professor Osler, after upbraiding the civic authorities of Baltimore for the laxness of their measures to prevent the spread of consumption, proceeds as follows:

"Now, what is the remedy? It is simple. It is very easy. It is so simple and easy that we won't get it for a good many years. It is a sad thing to think of, but it will be five years yet before we get a law compelling notification of cases of tuberculosis to the Health Board in Baltimore. Yet we all know there should be notification and careful inspection in every single case. It works no hardship to have the Board of Health know that a case exists in the family, even in the best house of Mount Vernon place. It can be done quietly and easily, without placarding or making the patient feel that he is a social outcast. It can be done properly and easily under systematic management."

THE MEDICAL RECORD has always staunchly championed the cause of the consumptive, and of the needy consumptive in particular.

The notification of pulmonary tuberculosis—at any rate among the poorer classes, who live in close contiguity and are thus peculiarly subjected to the influence of the microbe—is a measure to be taken in the interests of public safety.

Sanatoriums for the treatment of consumptives alone have now decisively proved their worth, and the erection of such public institutions in the vicinity of every large city is an act of self-preservation on the part of its inhabitants.

THE PARASITES OF MALARIAL FEVER.

Dr. Charles Craig, U. S. A. Director of the Laboratory of the Army General Hospital, Presidio, Cal., has published, in the report of that institution for 1901, a valuable contribution on the above subject, the results of his experience in bacteriological research during the fiscal year.

Five thousand eight hundred and fifteen specimens of blood were examined for the parasites of malarial fever, of which 643 were positive and 5,172 were negative. As to the etiology, the 643 positive cases may be divided as follows: Cases due to the benign tertian parasite, 220; to the quartan parasite, 3; to the æstivo-autumnal parasites, 400; to the tertian æstivo-autumnal parasite, 20.

Concerning the differentiation of the tertian and quotidian æstivo-autumnal parasites, Dr. Craig calls attention to the following conclusions by Marchiafava and Bignami: (1) Duration of life cycle, twenty-four hours in the quotidian, forty-eight hours in the tertian parasite; (2) Pigmentation, greater in the tertian; the pigment motile; (3) Size of parasite, greater in the tertian; (4) Amœboid motion, more marked in tertian and longer preserved; (5) Relation of the various forms to the life cycle. Most of these conclusions were confirmed at Presidio, and Dr. Craig—in the numerous cases of both varieties studied there—has been able to trace marked differences in every developmental stage of the parasites.

1. The Hyaline Stage.—The tertian æstivo-autumnal parasite is larger, more clearly cut and refractive, and has a more sluggish amœboid motion than

the quotidian parasite. It has often a signet ring shape, while the quotidian is perfectly round. Only the parasite is found, as a rule, in a corpuscle in a tertian infection, while in the quotidian two or more are common. The infected corpuscle is less crenated and lighter in color when infected by the tertian parasite.

2. The pigmented parasite is larger, and pigmentation occurs while the ring form is still retained. In the quotidian the ring form is never pigmented. Amœboid motion is present after pigmentation, while in the quotidian it is always lost before pigmentation occurs. The tertian parasite is more sharply defined and the pigment present is in larger amount, is finer and is motile, while in the quotidian the pigment is always motionless, and consists of one or two coarse granules. Only one pigmented tertian occurs in a corpuscle, while two or more quotidian parasites may be present in one corpuscle. The infected corpuscle is more crenated and brassy when infected by the quotidian parasite.

3. The Segmenting Stage.—The number of segments is greater in the tertian and the segments are more oval in outline and larger. Segmentation occurs outside the red corpuscle in the tertian æstivo-autumnal parasite, while in the quotidian it occurs within the infected corpuscle.

4. The Crescentic Stage.—The tertian crescents are longer and more narrow than the quotidian, are more deeply pigmented, and have less of a double outline. The protoplasm of the tertian crescent is more refractive and granular in appearance.

5. The Flaggelated Stage.—In the tertian parasite both forms of flaggellate bodies heretofore described are larger and more deeply pigmented than in the quotidian.

6. The Cycle of Development.—Twenty-four hours completes the cycle of development within the human body in the quotidian parasite. Forty-eight hours in the tertian.

Dr. Craig definitely concludes that there are at least two varieties of the æstivo-autumnal parasite, a tertian and quotidian.

This view, held by many skilled observers, is in opposition to the opinions of others, who argue that the differences noted may be due to special conditions of environment, or unusual factors affecting the health of the individual, etc.

There would seem to be no means of actually proving the point one way or the other, but, as Dr. Craig remarks, the differences are so constant and harmonious that it is impossible to believe that they are accidental.

Decline in the British Birth Rate.

France has been for some years pointed at as a country on the down grade, because her population has remained almost stationary, on account of the remarkable and progressive decrease in the number of births. Other countries have declined in birth rate to some extent, and among the American-born inhabitants of the United States the proportion of births to deaths is by no means so satisfactory as was the case even ten years ago.

In the *Fortnightly Review* for April, Mr. Edward Canaan contributes a pessimistic paper upon the marked decline in the birth rate of Great Britain.

The writer maintains, from the showing of recent statistics on the subject, that the English are becoming like the French, are ceasing to increase and multiply, and that unless the British Empire can bring within its boundaries a prolific foreign element, and a continuance of the present condition of things be stayed, that Great Britain must lapse from her present high estate and fall into the category of second-class nations.

In order to permanently keep in a stationary position as regards population, it is necessary that the average number of children born from each marriage should be a little over three. The ratio in Great Britain of children per marriage has fallen from 4.36 in 1884 to 3.63 in 1900. At this rate of decrease another sixteen years would dry up the sources of the natural increase of population.

Already Great Britain is, perhaps, full enough of people, but consolation has always been found in turning to her colonies as a refuge for her surplus population. There, at least, is plenty of room in which to live and rear children in practically unlimited numbers,

But Mr. Canaan draws attention to the fact that the British do not appear anywhere to beget progeny as in times gone by, and that in the colonies the children are not of British descent.

Canada for example. The total increase of population in the Dominion, including the gain by immigration as well as by natural increase, has fallen from 839,000 in the decade ending 1880 to 506,000 in that ending 1901.

On the other hand, the French population of Canada has maintained its usual increase.

With regard to Australia the same story has to be told. The birth rate is low and declining. In 1891 Australia, including New Zealand, with a total population of 3,750,000, had 126,000 births; in 1898 only 112,805, while in 1899 a rise in the number of births of but 2,000 was registered.

The inference to be drawn from a study of these facts would seem to be that the fertility of the British race is not what it used to be.

Centralization of Medical Work in Washington, D. C., Desired.

The Medical Society of the District of Columbia has sent a memorial to the Commissioners of the District urging that all matters relating to medicine and sanitation be placed under the control of the health officer. The work of a medical character under the municipal authorities is now directed from a number of sources and includes the following classes:

The administration of the affairs of the Health Department; the administration of the medical affairs of the Washington Asylum and workhouse; the examination of applicants for appointment in the police and fire departments; the treatment of the sick and injured of those departments and of sick prisoners in station-houses; the treatment of sick poor at their homes; the examination of applicants for hospital treatment at public expense; the examination of persons for licenses to practise medicine, dentistry and pharmacy; and the examination of persons alleged to be insane, with a view to their commitment to the insane asylum.

In urging this reform, the Medical Society says that it is unable to find any reason why the medical work of the District of Columbia should be divided among so many departments and offices of the government, while all legal work is concentrated in the office of the city solicitor and all engineering work in the engineering department.

High and Low Death Rates.—Guatemala has the highest death rate of any country in the world. Its death rate is 41 per 1,000. In New Zealand the mortality is only 11 in the 1,000.

News of the Week.

Mount Sinai Hospital, N. Y.—Dr. Joseph Brettauer has been appointed Attending Gynecologist at the Mt. Sinai Hospital to succeed the late Dr. Paul F. Mundé.

Rush Hospital for Consumptives.—The trustees of the Rush Hospital have secured for use as a country branch a farm of forty-seven acres [illegible] which [illegible] in Willistown Township, Chester Co., Pa., situated about [illegible] feet above sea-level. The improvements consist of a new three-story frame dwelling, [illegible] feet, containing [illegible] rooms, a stone dwelling containing nine rooms, a large barn, an engine house, an ice house, a large spring house with a good spring, etc. It is intended to receive at the country branch only incipient cases of tuberculosis, in the treatment of which fresh air, good hygiene, and nutritious food are most valuable. It is the purpose of the trustees, if this plan proves successful, to build small cottages on the ground similar to those at the Saranac Sanitarium in the Adirondacks.

Philadelphia County Medical Society, North Branch.—At a stated meeting held April 17, Dr. W. Wayne Babcock presented a communication entitled "Microscopic Diagnosis of the Abnormalities of the Blood," in which he detailed methods of estimating hemoglobin, of enumerating red and colorless corpuscles, of differentiating the latter and of demonstrating the presence of malarial parasites, such as can be carried out by the general practitioner. Dr. R. L. Pitfield read a paper entitled "The Use of Simple Microscopic Methods by the General Practitioner," dwelling upon the importance of systematic examinations of urine (chemically and microscopically), of sputum (for tubercle-bacilli and pneumococci), of blood, and of deposits in the pharynx. The discussion was continued by Drs. J. Dal and F. A. Packard, Jos. Sailer, A. A. Eshner, and M. H. Fussell, who referred to examinations of the fresh blood, of the stools, of the nasal discharges, and to the Widal test.

The Status of Vaccinators of the Board of Health.—Some time ago a number of vaccinators were discharged by a health commissioner of the city, because the appropriation was insufficient to pay all those employed. One of the number sued for reinstatement on the ground that he could be dismissed only on charges brought by the Commissioner and sustained on trial. The court decided that employees of the department could be discharged, without other explanation, whenever the payroll was too large for the appropriation.

Delegates to Convention of Red Cross Society.—Six delegates have been appointed to represent the United States at the international convention of the Red Cross Society, which opens at St. Petersburg on May 29 for a three weeks' session. The delegates appointed are ex-Surgeon-General W. K. Van Reypen, U. S. Navy, Captain S. L. H. Slocum, U. S. Army, Military Attaché at the U. S. Embassy, St. Petersburg, Dr. Nicholas Senn of Chicago, late chief surgeon U. S. Volunteers, Mr. B. T. Tillinghast of Iowa, Miss Clara Barton, President of the National Red Cross Society, and Mrs. J. Ellen Foster of Washington, D. C.

Guilty of Misdemeanor.—Surgeon F. H. Marsteller, U. S. Navy, was recently tried on charges of drunkenness on duty, found guilty, and sentenced to be suspended from rank and duty for two years, to receive, during this period, one-half his shore pay, and to have his promotion retarded by being reduced five numbers. In acting on the record, the Secretary of the Navy says that the sentence imposed was entirely inadequate, and in the army would have resulted in the officer's dismissal from the service. He also criticises the sentence in that it relegates to idleness for two years an officer whose services are needed, and throws the performance of his work on others.

Complimentary Dinners to Surgeon-General Sternberg.—A complimentary dinner to Surgeon-General and Mrs. Sternberg will be given in Washington shortly before the coming retirement for age of General Sternberg on June 8, by the army medical officers and their families stationed in or near that city. The Army Medical Corps feels under the greatest obligation to General Sternberg for what he has done, during nine years' service as its chief, to improve its professional status and military efficiency.

In view of the fact that the army dinner is to be a purely "family affair," given by General Sternberg's military associates, a testimonial banquet in his honor, in special recognition of his great contributions to medical science, is to be given in New York by the most prominent medical men of the United States. Professor William Osler of Johns Hopkins University is in charge of the banquet.

The Secretary of the Navy has transmitted to Assistant Surgeon Raymond Spear, U. S. N., attached to the *Concord*, a copy of a letter from the government of Colombia, thanking him "for valuable services rendered to the wounded Colombian soldiers in the late conflict on the line of the Panama Railroad." Surgeon Spear landed at Panama with 350 marines and blue-jackets in December last, and crossed and recrossed the isthmus with them in their effort to protect the railroad and keep communications open. Upwards of 200 of the native contending forces were wounded during the fighting near the railroad line, and nearly all of them came under the professional care of Surgeon Spear.

Philadelphia County Medical Society.—At a stated business meeting, held April 16, thirty-one new members were elected, numerous verbal amendments to the by-Laws were adopted, the names of thirty-seven candidates for membership were read, and resolutions were adopted commending the administration of the Municipal Hospital at the hands of Dr. Wm. M. Welch and his corps of assistants.

The Continental Anglo-American Medical Society.—It has been proposed that a luncheon of this society shall be held every year at the time and place of meeting of the British Medical Association, and accordingly one will be held this year at Manchester in July.

St. Mark's Hospital in this city was recently seized by the sheriff to satisfy a judgment obtained against it by a manufacturer of surgical supplies. The hospital was not closed, however.

A New Application of the Radiograph.—Certain criminals possess great flexibility of their facial muscles, and so modify their expression when being involuntarily photographed in prison that the portrait can hardly be recognized as that of the prisoner when the latter assumes his ordinary appearance. To get rid of this trouble the French authorities now require that a radiograph be taken of each prisoner. Whatever power he may have of modifying his facial expression, the criminal has no chance with the radiograph; his bones are not amenable to the influence of his will momentarily exerted during his exposure to this, the latest resource of civilization for combating crime.—*Medical Press.*

Dr. Knopf's Prize Essay on Tuberculosis.—Three hundred thousand copies of the German edition of

"Tuberculosis as a Disease of the Masses," by Dr. S. A. Knopf of this city, which received the prize of the German Tuberculosis Congress, have been printed and distributed. The essay has been translated into English, French, Italian, Spanish, Portuguese, Dutch, Russian, Polish, Bulgarian, Roumanian, Hungarian, and Jiddish, and published in fifteen different countries. The right of translation and publication in any language is freely granted in the interest of humanity.

American Climatological Association.—The nineteenth annual meeting of this society will be held at Los Angeles, Cal., on June 9-11, under the presidency of Dr. Samuel A. Fisk of Denver. The secretary is Dr. Guy Hinsdale, 3943 Chestnut street, Philadelphia. In connection with the meeting a tour has been arranged, under the management of Raymond and Whitcomb, by which members of the association will be enabled to investigate at first hands the true conditions of the Rocky Mountain and Pacific Coast regions, for which so much is claimed in the way of climatic advantages. The tour will extend from May 26 to July 3, for eastern members, and proportionately less for those who western cities.

The Seventy-fourth Annual Congress of German Naturalists and Physicians will be held at Carlsbad, Austria, on September 21–28, 1902. It is estimated that more than six thousand persons will take part in the deliberations of this Congress, the work of which is distributed through twenty-eight sections. It is a rule of the Congress that papers may be read and discussed in any language whatever, and physicians and naturalists from any part of the world are accorded the same privileges as those enjoyed by the regular members of the association, and it is hoped that there may be a numerous attendance of English and American visitors. Those desiring to read papers or intending to take part in the work of the Congress are requested to give notice of their intention at an early date, directing their communication to "The 74th Congress of Natural Philosophers," Carlsbad, Austria.

International Congress on Electro-Therapeutics.—The first International Congress on electro-therapeutics and radiography was held in Paris in the summer of 1900. At that time it was voted to hold an International Congress periodically every three years, but to avoid clashing with other congresses, it was resolved that the second Congress be held in 1902 and at Berne. The following international committee was then elected and charged with the arranging of future congresses: *President*, M. Tripier, Paris; *Secretary*, E. Doumer, Lille; *Assistant Secretary*, A. Moutier, Paris; *Treasurer*, Boisseau du Rocher; Benedikt, Vienna; R. G. Brown, Brooklyn, N. Y.; Chatzky, Moscow; Dubois, Berne; Grunmach, Berlin; La Torre, Rome; Leduc, Nantes; Provost, Geneva; Schiff, Vienna; Weiss, Paris, and W. Salomonson, Amsterdam. The Congress will open on September 1 and continue for six days. The subjects announced for general discussion are: 1. The Present State of Electrodiagnosis; 2. Surgical Electrolysis; 3. Radiography and Radioscopy of the Internal Organs; 4. Accidents Caused by x-rays; 5. The Danger of Industrial Electric Currents. The membership fee is 25 francs ($5.00), which should be sent with the applicant's visiting-card to Dr. Schnyder, 38, Rue Féderale, Berne, Switzerland.

Smallpox at Saranac Lake.—Dr. J. H. Hallach writes that the report that "Cuban itch," or any other disease for which smallpox is sometimes mistaken, prevails at Saranac Lake, is incorrect. There have been only three cases of smallpox or anything resembling it in the town, and these were imported.

Association of French-Speaking Physicians of North America.—The first meeting of this newly-founded society will be held in Quebec on June 25–28, in the buildings of Laval University. Over six hundred physicians from Canada and the United States have announced their intention to take part in the proceedings, and France will also be officially represented.

The Society of the Alumni of the Presbyterian Hospital in the City of New York was incorporated under the laws of the State on April 16, 1902. At the annual meeting, held at the Presbyterian Hospital on April 12, the following officers were elected for the ensuing year: *President*, B. Van D. Hedges; *Vice-President*, David Bovaird; *Secretary*, John Howland; *Board of Directors*, Henry L. Shively, William K. Simpson, Arthur M. Jacobs, John A. Hartwell, and Forbes Hawkes. The next meeting of the Society will be held at the Arena on Saturday evening, May 17, at 7.30 P.M. Dr. Charles K. Briddon will address the Society at that time on "Reminiscences of Half a Century in Medicine and Surgery."

The Committee on Pathological Exhibits for the American Medical Association is anxious to secure materials for the coming session at Saratoga, June 10 to 13, inclusive. This exhibit was accorded much praise and comment during the sessions at Atlantic City and St. Paul, respectively, where were collected valuable exhibits from all parts of the country. The materials included not only pathological specimens, but the allied fields, bacteriology, hæmatology, physiology, and biology, were well represented. It would also be desirable to secure exhibits of new apparatus, charts, etc., used by teachers of pathology and physiology in medical colleges. This exhibit has already become a permanent feature of the annual sessions of the American Medical Association, and the committee is desirous of securing its lists of exhibits as early as possible, and to this end, asks those having desirable materials to communicate with any member of the committee. To contribute to the value of the work, it is suggested that, as far as possible, each contributor select materials illustrative of one classification, and, by such specialization, enhance the usefulness of the display. Those lending their materials may feel assured that good care will be given their exhibits while in the hands of the committee, and due credit will be given in the published reports. The members of the committee are: F. M. Jeffries, 214 East Thirty-fourth Street, New York City; W. A. Evans, 103 State Street, Suite 1403, Chicago, Ill.; Roger G. Perkins, Western Reserve Medical School, Cleveland, Ohio.

Philadelphia County Medical Society.—At a stated meeting, held April 23, Dr. Joseph Price read a paper entitled "Operations on the Green Groin (Appendicitis)." He discussed especially the subject of gangrenous appendicitis and the necessity for prompt and radical surgical treatment. Dr. Robert N. Willson presented a communication entitled "The Analyses of Fifty Cases of Tetanus Following Vaccinia, with References to the Sources of Infection." He had collected both from the literature and from private sources, as many of the cases as possible in which tetanus had developed in the sequence of vaccination, and in none was the evidence convincing that the complication was due to direct inoculation with the vaccine virus. It rather appeared that the tetanus was the result of accidental secondary infection, for which there was abundant opporrarely, and the fact that the interval between the vaccinal inoculation and the development of the symptoms of tetanus was almost invariably longer than the incubation period of tetanus seemed to lend support to this view. Dr. Jos. McFarland read a paper entitled "The Relations of Tetanus to Vaccination." He pointed out that while for many years tetanus developed only in isolated cases in the sequence of vaccination, a much larger number of cases occurred during the year 1901, and of these the preponderating number followed the use of one particular manufacturer of lymph and not within any local geographical distribution. From personal observation Dr. McFarland was able to state that all of the larger establishments for the manufacture of vaccine-virus are provided with the most modern scientific apparatus and are conducted with the greatest regard for cleanliness and antiseptic precautions, being, as a rule, under the charge of able and trustworthy bacteriologists of the highest order of skill, so that if contamination of the virus was the responsible factor for any of the cases of tetanus this year, it must have been due to temporarily unavoidable conditions. The fact that so small a number of cases of tetanus had developed in the sequence of vaccination under all circumstances among the enormous number of vaccinations practised was an indication of the small degree of risk attending the protective operation, and this can be still further reduced by scrupulous attention to surgical antiseptic detail. Dr. F. A. Packard proposed the appointment by the Philadelphia County Medical Society of a commission through whose hands should pass, periodically, samples of vaccine-virus offered to the profession for consumption, in order that the freedom from contamination of such virus may be established and be properly certified to in order that the practitioner may know in every instance, so far as possible, that the virus that he is employing is safe beyond peradventure.

Obituary Notes.—Dr. Theodore Walser of this city, assistant sanitary superintendent of the Department of Health, Richmond Borough, died at his home in New Brighton, last week, after an illness of three weeks. He was seventy-seven years old. Dr. Walser was a native of Germany, was graduated from the Jefferson Medical College in 1851, and had practised in New Brighton since 1857. He held many public-health offices. In the early sixties he was deputy health officer of the port of New York. For many years he was health officer of the old village of New Brighton and held that position until the village was incorporated into Greater New York. He was one of the founders of the S. R. Smith Infirmary. Dr. Walser was the third assistant sanitary superintendent to die while holding that office in the past four years. Dr. George G. Hubbard died after having held the office only six months. His successor, Dr. John L. Feeny, died in May, 1901. He left a son, a physician, and a daughter, the wife of a physician.

Dr. George E. Harrison of Springfield, L. I., died in St. Luke's Hospital in this city, on April 24, from disease of the heart. He was born in Cleveland, Ohio, forty-nine years ago. In 1873 he entered the Naval Academy at Annapolis from the Second Congressional District, Michigan. He left at the end of his third year to study medicine, and was graduated from the Bennett Medical College, Chicago. Dr. Harrison was a traveler and a hunter of big game, and was a frequent contributor on hunting topics to the magazines. He was a member of the Press Club of this city, of the Grosvenor Club of London, and a charter member of the American Society in London.

Dr. Joseph P. [illegible], one of the oldest of the alumni of the University of Pennsylvania, died in Trenton, aged seventy-nine years. He was in the cavalry service in the Civil War. He was in practice for over fifty years.

Dr. F. R. Thomas of Pueblo, Col., died at his home in that city on April 17, at the age of sixty-two years. He had graduated from the Rush Medical College, Chicago, in the class of 1862, and immediately entered the army, serving on the medical staff until the close of the Civil War. Soon after that he removed to Pueblo, where he practised his profession until shortly before his death. For several years he was superintendent of the State insane asylum.

Dr. [illegible] [illegible] died in Philadelphia on April 19, at the age of fifty-five years. He was a graduate of Jefferson Medical College, and was one of the physicians to the Jefferson Hospital.

Dr. J. T. V. [illegible] of Wilmington, Del., committed suicide by strangulation at the State Hospital for the Insane at Farnhurst on April 15. He was born in Sussex County, Delaware, in 1850, and was graduated from Jefferson Medical College in 1874.

Obituary.

FREDERICK A. CASTLE, M.D.,

NEW YORK.

Frederick A. Castle, M.D., of New York, died April 28, 1902. He was born at Fabius, N. Y., April 29, 1842, received his preliminary education at Rochester, N. Y., and graduated at Bellevue Hospital Medical College in 1866. He served as medical cadet, U. S. Army, 1862-1863, and as acting assistant surgeon, U. S. Navy, 1863-1865. After graduating, he established himself in general practice in New York. He was editor of *New Remedies*, afterwards the *American Druggist*, and did considerable other medical literary work. For a considerable period previously to this he was a valued member of the editorial staff of the Medical Record. For a time, also, he was a lecturer on pharmacology at Bellevue Hospital Medical College. His thorough knowledge of this branch of medicine secured for him the well-deserved compliment of selection as a member of the committees for the sixth and seventh revisions of the U. S. Pharmacopœa, and for membership in a large number of medical and scientific societies. In 1877 he was appointed Visiting Physician to the Presbyterian Hospital, serving in that capacity for ten years. He was also a member of several clubs, in the organizing and management of some of which he was specially active. Early in his career he connected himself with the County and State Societies, and the New York Academy of Medicine, serving in the latter as treasurer and member of the Board of Managers. As one of the Building Committee of the Academy he was very prominently identified with the construction of the present edifice. It was largely through his personal efforts with influential friends that substantial additions were made to the building fund, thus making possible the necessary elaboration of initiatory plans. Notwithstanding his multifarious duties as medical editor, lecturer, hospital physician, and frequent contributor to medical literature in general, he engaged himself in active private practice, and was, in every sense, a broad and cultured medical man. He was a hard and efficient worker during his entire career, and leaves behind him the memory of duty well done and honors well won.

Correspondence.

OUR LONDON LETTER.

(From Our Special Corrrespondent.)

PARLIAMENT — ASYLUMS BOARD — LOCAL GOVERNMENT BOARD AND GREENWICH SCANDAL—TUBERCULOSIS OF UTERUS — DISINFECTANTS — CULICIDÆ — CANCER RESEARCH—ROYAL ORTHOPÆDIC HOSPITAL AGAIN—OBITUARY.

LONDON, April 11, 1902.

THERE has not been much of interest in the House of Commons, which resumed on Monday. Questions on vaccination statistics, on lymph obtained from monkeys, the cost of the smallpox epidemic, and so on, were put, mostly, with a view of gratifying the anti-vacs, but the answers were not calculated to produce that effect. In reference to the last point, it was stated that the expenditure of the Asylums Board, incurred through the epidemic, in the half year ending March 31, amounted to £280,000. No information had been obtained as to the amounts expended by Boards of Guardians and other local authorities.

The discontent with the Asylums Board has been growing, and at length seems to be justified by the chairman of its finance committee, whose recent statements have given rise to protracted discussions. People who pay want to know why with an increase of ninety-nine patients the increase of expenses ran up to more than £200,000? Further, why the weekly cost per patient at one of the board's hospitals should be £1.9.10, and at another £2.11.6? I have previously referred to the extraordinary expenditure on buildings and the discrepancies connected therewith. The board will have to be reformed or abolished—preferably the latter—for its constitution is anomalous and its administrative efficiency deplorable.

The Local Government Board, too, had better mend its ways; under its orders Greenwich has been compelled to build a new work-house, and that in spite of protests on the part of the guardians. This week the new building has been formally handed over, and is described as a palatial edifice, more fit for a first-class hotel than a home for paupers. The cost is said to exceed £300,000, and now the local board has changed its policy and prefers boarding out. So the poor ratepayers' money is gone, and the palatial building is to let.

Tuberculosis of the uterus is so rare that the proceedings of the Obstetrical Society on the 2d inst. possess unusual interest. Specimens of the affection were shown by the president (Dr. Horrocks) and Drs. Williamson, Targett and Croft.

Then Dr. Lewers read an account of a case of primary tuberculosis of the cervix which simulated cancer so closely that, believing it to be so, he performed vaginal hysterectomy on January 30, 1896. Dr. Lewers has seen the patient several times since, and last November she wrote to him that she was enjoying "good health and had had no return of bleeding." Portions of the growth were sent to the Clinical Research Association, and the report came back that there was no evidence of cancer, but that the structure was tuberculous.

Dr. Handfield-Jones said he had met with a similar case in a patient who had suffered from tuberculous arthritis of the fingers for which some had been amputated. She had hemorrhage and discharge, and an excavation of the cervix extending down to the vagina was found on examination. Tubercle bacilli were found in the discharge. Radical operation was declined, so, under an anæsthetic, the ulcer was thoroughly scraped and Paquelin's cautery applied. The patient remained well, so far as the pelvic symptoms were concerned. Her doctor reported that no trace of the growth could be felt, but she had developed pulmonary phthisis. The question arose whether this treatment would be sufficient in other cases.

Dr. Targett, remarking on the rarity of tuberculosis in the uterus suggested that most cases were due to extension from the tubes, where it was so much more common—from 10 to 15 per cent. of cases of tubal disease being tuberculous. In nearly all cases when the uterus was affected the growth was found also in the tubes and at an earlier stage. Uterine tuberculosis was nearly always associated with perimetritis, leading to extensive adhesions, which made removal of the uterus very difficult. But he doubted if curetting would do any good.

Dr. Croft commented on the close resemblance to cancer of the clinical symptoms and mentioned a case as to which he was at first puzzled, but which proved to be tuberculosis.

Dr. Kerr suggested that the growth in Dr. Lewers' case might possibly have been secondary to pulmonary tuberculosis.

Dr. Horrocks (president) said that even the microscopic appearances were not always decisive. There was, however, a difference which he had noted in two cases of tuberculosis, *viz.*, the growth affected the whole of the interior of the uterus, body, and cervix alike; this was scarcely ever the case in cancer.

In the report of the County Council's Medical Officer, just distributed, there is an account of some investigations by Drs. Klein, Houston, and Gordon on disinfection under conditions similar to those met with in ordinary dwelling houses. The results are rather unexpected, and will probably give rise to other experiments in the interests of those whose products seem the least effectual Cloth, unpainted wood, linen and wall paper were charged with microbes and exposed to the action of different disinfectants. Formalin and sulphur dioxide failed in the case of cloth and wood charged with spores. Formalin was more active than the sulphurous gas on tubercle sputa dried on linen and paper. Turning to fluid disinfectants it seems that corrosive sublimate was most effectual, for twenty-four hours exposure with 1 in 1,000 destroyed all microbes, including spores of anthrax and the bacillus of tubercle. Five per cent. carbolic acid, with the same time of exposure, destroyed all except anthrax spores. Bleaching powder was more destructive to anthrax spores on paper and linen, but in other cases was less active than carbolic acid. The bacillus of typhoid was destroyed by all the disinfectants except bleaching powder and permanganates. A similar result is reported with these two on the cholera vibrio and on staphylococus aureus. The other disinfectants were efficacious in these cases. Practically, it would seem that Condy's fluid is of inappreciable value and bleaching powder must take a back seat. Sulphurous acid, too, has not sustained its reputation, being useless against tubercle bacillus, as were also Condy's fluid and formalin; in fact, for this organism only carbolic acid and corrosive sublimate were of value, and for anthrax spores the sublimate only.

A "Monograph of the Culicidæ on Mosquitos," by F. V. Theobald, M.A., has been brought out for the trustees of the British Museum, in three volumes, with numerous illustrations, maps, and colored plates. It is published for the trustees by Longmans at £3.3.

Major Ronald Ross has written a small volume entitled "Mosquito Brigades, and How to Organize Them," just the thing to suit such of the public as are interested in the prevention of malaria.

A number of other works on this subject are exciting attention—among which I may mention "Reports to the Malarial Committee of the Royal Society," by Dr. Christophers.

The two colleges have arrived at a draft scheme for an organized research on cancer, which I wrote you was proposed. The General Committee seems well constituted, the Scottish and Irish Royal Colleges are to have representatives, and so are the veterinary colleges. The Colonial Office and the Royal Society are each to be invited to nominate a member.

You have heard so much of Mr. Rhodes's will that I refrain from further remark than that Oxford now has the chance of making her medical school worthy of her reputation.

Surgeon-General J. C. Penny, M.D., London., died on the 6th inst., aged seventy-two years. He had a distinguished career in India, was through the mutiny and took part in the relief of Lucknow and Cawnpore.

Deputy Inspector-General J. T. Caddy, R. N. (retired), died on the 21st ult., aged eighty years, after thirty-one years of naval service, he had a Greenwich Hospital good-service pension.

The death of Surgeon-Captain Geo. Ramsay of the Indian Medical Service, at the early age of thirty-three years, is also reported. He had the Chitral medal and clasp.

Robert Brown, F.R.C.S., on the 28th ult., in his eighty-second year.

William J. Preston, M.D., on the 16th ult., aged eighty-two years.

Only last week I told you of the death of Dr. Long Fox. Now, I have to record the death of his much younger brother, Dr. Bonville Fox, who died on the 2d inst. He was only forty-nine years old. He had devoted much attention to lunacy, and was proprietor of a private asylum near Bristol, where he was a well-known figure. His opinion in consultation was highly valued, and he had the esteem of his brethren.

Faculty of Medicine at Columbia.—The first faculty of medicine at Columbia University was established in 1767, and reestablished in 1792, five years after the war was over and the college had been reopened. The medical faculty was merged in the College of Physicians and Surgeons in 1813, the course being given at Columbia. In 1860 the School of Physicians and Surgeons became the medical department of the college, although not actually a fundamental part of the institution.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 24, 1902.

Notes on the Production of the Test Serum in Rabbits.—W. F. Whitney [illegible] with the extreme of care and experience. But considerable experience must be had before one would be [illegible] in a criminal case.

The Serum Test for Blood.—E. S. Wood says that the first discovery of blood [illegible] was made by [illegible], whose method and work has been confirmed and extended by other investigators. It has been found that rabbits are the animals best suited for this kind of experimentation. If a rabbit is prepared by injecting into the peritoneal cavity several times, at intervals of a few days, about [illegible] of any kind of blood or blood serum, there will be formed in the blood of that animal a peculiar body, called by Myers and Nuttall a precipitin, which will produce a precipitate [illegible] the precipitum in the diluted blood or blood serum of an animal of the same kind as the one with which the rabbit was prepared. Recently the author applied the test with antiserum obtained from a [illegible] rabbit in a murder case. Solutions of blood stains found on clothes, towels, a stone, etc., were placed in small test tubes side by side, and when to them was added two or three drops of the test serum, a distinct precipitate occurred within half an hour. This reaction did not take place in test tubes containing blood of the dog, pig, ox, and sheep, which had been prepared for purposes of comparison.

Journal of the American Medical Association, April 26, 1902.

Surgery of the Liver.—Carl Beck of Chicago gives the clinical histories of several cases and reviews certain experimental researches made by himself and by others. From his observations on patients and from experiments on animals, he would draw the following conclusions: (1) Liver tissue of considerable size may be safely removed by previous anemization of the part which is intended to be removed. (2) For the support of the ligature, living tissue from the same animal, preferably the fascia and peritoneum from the abdominal wall, is best suited. (3) The intraperitoneal or the intraparietal method is preferable to the external method.

The Nature of Prostatic Hypertrophy.—R. H. Greene and Harlow Brooks discuss this question in an elaborate paper which is freely illustrated. They have collated [illegible] cases, all showing evident inflammatory lesions. The most frequent cause of enlargement was found to be interstitial hyperplasia. Their main conclusions are as follows: (1) Prostatic hypertrophy of the aged is the result of chronic prostatitis. (2) It most frequently arises from chronic posterior urethritis of whatever cause. (3) True neoplasms of the prostate are rare and are not concerned in the production of prostatic hypertrophy. (4) Carcinoma is apt to occur in the hypertrophied prostate as a result of the chronic inflammatory process.

The Relationship of Antistreptococcus Serum to the Treatment of Puerperal Sepsis.—G. E. R[illegible] relates the history of an unsuccessful case and does not believe that the serum is a proper remedy to administer under the circumstances indicated. His patient died in uremic convulsions. No pus accumulations could be discovered and this condition the author attributes to the frequent and persistent use during the case of hot vaginal douches. As things to be avoided in general, he mentions the [illegible] ether anesthesia, when narcotics may be required, exploring with trocar for pus, cauterizing abraded surfaces to destroy exudation, making an abdominal incision during the course of the septic fever unless the pus accumulation has become localized and demonstrated, or making it even then until after leucocytosis had been determined. He advises against subjecting the patient to the shock of any operation until the pus has formed and become localized and can be easily removed without severe shock to the system.

Management of the Umbilical Cord.—C. A. [illegible] with two ligatures. The ends are then cut off rather short, and a large sponge of cotton saturated with alcohol is placed on the navel, which is put in place by the nurse [illegible] the child to [illegible]. When the bath is given, the child is placed on its back in a tub that is only partly filled with water, or the child is washed with a sponge. After the bath fresh alcohol is placed on the navel when the child is being dried and [illegible]. Then a dry sterile pad of gauze or cotton is placed over the navel and the usual bandage applied. This pad stays in place without trouble till the next dressing of the child. As a rule, the child is bathed and the navel attended to every twenty-four hours. At the subsequent dressings a cotton sponge, saturated with alcohol, is applied before the bathing and also afterward. Then a dry dressing is used. The cord comes away in from three to six days.

New York Medical Journal, April 26, 1902.

A Peculiar Symptom in Typhoid Fever.—W. C. [illegible] calls attention to a symptom which he has found to indicate great danger and, as a rule, to presage death. It is unilateral deafness. But when, on the contrary, both ears are deaf the prognosis is generally favorable. This idea was advanced by Trousseau over twenty-five years ago, and [illegible] is unable to give any explanation of it, but claims to have verified its accuracy in his own personal experience.

On Blood Pressure under the Influence of Acute Overstraining of the Heart.—From an extensive series of experiments Theodore Schott has determined that during violent exercise, such as wrestling, the heart dilates, first the right ventricle, then the left; the pulse becomes small, rapid, very compressible, and even dicrotic. After cessation of exercise the conditions return to the normal, the time depending on the age and general state of the subject. Further investigations have shown that wrestling when not pushed to the point of dyspnea resembles a simple strong muscular action producing a rise in the blood pressure of from a few millimeters up to 10 or more. As soon, however, as a larger dyspnea appears the blood pressure rapidly sinks. With the cessation of the dyspnea and the disappearance of the cardiac dilatation the blood pressure does not necessarily return to normal, for the pulse may show variations from the normal for a long time and, similarly, the blood pressure may require hours before regaining the normal height. In other cases the arterial blood pressure returns very quickly even when the pulse and respiration rates are still high. The cardiac dilatation, however, always becomes normal by that time. It has also been found that when in a healthy man the experimenter has produced an acute insufficiency of the heart by muscular exertion—for instance by wrestling—if he repeats the experiment after not too long a period, far less effort and far shorter duration of exercise are sufficient to reproduce the cardiac insufficiency. According to Schott these observations throw an explanatory light upon the origin of chronic cardiac insufficiency.

American Medicine, April 26, 1902.

Pneumonia.—Stephen Smith Burt defines pneumonia as an acute, self-limited, systemic infection whereof the concomitants, though various, are chiefly pulmonary; it is endemic in many countries and it occurs everywhere sporadically; regarding the lung tissue, the affection seems more in the nature of an exudation than an inflammation; the frequency of detection of the diplococcus in living blood in pneumonia suggests that by improved technic it will be found, like the plasmodium in malaria, invariably; infection of the heart muscles with resulting degeneration has more to do with heart failure than mechanical obstruction; the exact significance of pathological leucocytosis requires further elucidation; pre-existing receptivity determines the degree of infection, rather than the number of microbes, which are in quality unchangeable; while neglect of personal hygiene and of sanitation predisposes to pneumonia; unqualified good health is a protection therefrom.

Mentholization of the Mucosa of the Air Passages.—W. A. Briggs advises this procedure as a preliminary to etherization. He describes the method as follows: Sprinkle a drachm of oil of peppermint or of saturated solution of menthol in the cone; let the patient inhale the fumes for three minutes, then saturate the cone with ether and bring it down slowly over the face; after a few full inhalations, crowd the cone down and push the etherization as rapidly as can be done with safety. Use the same cone throughout the anæsthesia. After the operation let the patient inhale the peppermint or menthol from a handkerchief till the tendency to nausea subsides. The advantages of the menthol are entire freedom from cough and sense of impending suffocation and comparative freedom from nausea, vomiting, and retching; the ease and rapidity with which anæsthesia may be induced and the ease with which it may be maintained; the entire absence or marked abbreviation of the period of excitement; economy both of ether and of time; more profound primary anæsthesia, under which minor operations may be done with more certainty; and finally, probably less postoperative nausea and vomiting.

Marrow and Spleen Cells Considered in Their Relation to the Blood Cells.—Edward T. Williams describes marrow cells as round or ovoid, and from 15 to 20 microns in diameter. They contain a single large and usually excentric nucleus, varying in shape. This stains readily with the basic dyes. The cell body takes the same dyes, though less deeply. In fact, the true marrow cells are basophiles. The best pictures are obtained with alum-hematoxylin and Bismarck-brown, staining half an hour in hematoxylin, then washing thoroughly, and finally counterstaining with a dilute solution of Bismarck-brown. Hematoxylin and basic fuchsin also make a fine picture. The marrow cells are identical with the so-called large lymphocytes of the blood. The latter is the true myelocyte of the blood. The marrow cells are capable of amœboid movement, and the nuclei seem to be capable of a rotary movement. The marrow cells are in all probability the progenitors of the multinuclear leucocytes. The spleen contains red and white blood-corpuscles and multinucleated giant-cells resembling those of bone-marrow. The spleen-pulp as to its cellular elements closely resembles bone-marrow. Of all the spleen cells, the red blood-corpuscles are the most numerous. The white corpuscles are far less numerous in spleen than in marrow. The majority of these are small uninuclear cells, like the lymph cells. They are distinctly basophile. There are very many large uninuclear leucocytes, often twice the size of the lymphocytes, and nearly, if not quite, identical with the true marrow cells or myelocytes. Multinuclear leucocytes are comparatively rare in the spleen. Nucleated red cells are more numerous in spleen than in marrow. There are a great many microcytes and poikilocytes. As to the red corpuscles, the obvious conclusion is that they are elaborated by the spleen. The production of red corpuscles in the red marrow rests on much slenderer evidence and yet is universally admitted. The writer believes that the red blood-corpuscles are formed in the red bone-marrow, but that the spleen is also an active sharer in the work. As to the leucocytes, the spleen seems to have a less important agency in the formation of these bodies than the marrow and lymph glands.

Medical News, April 26 1902.

The Indications for and Limitations of the Bottini Operation.—According to Louis E. Schmidt, it is almost needless to state that this operation has suffered from the exalted enthusiasm of those who have recommended it for every case of prostatitis. On the other hand, it has been condemned by many surgeons who have never practised it. Authorities vary as to the exact indications. There are certain limitations of the prostatic pathological changes which, when operated on by this method, permit of good expectations as to the ultimate outcome. These changes of the gland, naturally, from the character of the operation, must occur just at the border between the urethra and the bladder. Absolute contraindications can be put forward only in those cases in which the anatomical pathological conditions preclude the possibility of any favorable result. The so-called "prophylactic" Bottini operation of Horwitz must always be followed by good results if the case be properly selected and if the technic be faultless. If it be not possible to make a thorough cystoscopic examination, it is best not to undertake the operation. Cicatricial contraction cannot occur if the barrier or barriers have been completely severed and if the technic is correct. As to phlebitis, anterior incision in the large majority of cases was the cause, and this has been practically abandoned. The Bottini operation is not an easy one. It is necessary to be able and willing to recognize at once any accident which may occur at the time of operation or any later complication. The after-treatment must be very careful. Good results of this operation will depend on the careful selection of cases; on the proper technic of the operation and proper after-care; and on the immediate correction of errors or mishaps.

The Diagnosis and Operative Treatment of Prostatic Hypertrophy, with Remarks on the Complications Before and After Operation.—Ramon Guiteras sums up the clinical and statistical data obtained upon the subject of prostatic operations during the last few years. He says the general practitioner should be educated to palpate the prostate, and to use the other simple means of diagnosis employed in determining the shape and size of the organ. In default of previous training in rectal palpation, he should at every opportunity familiarize himself with the feel of a normal prostate, and should thus educate his touch for prostatic diagnosis. The prostate corresponds pathologically in the male to the uterus in the female, and its examination is just as important. In prostatics, the care of the bladder before operation is a prime factor. The importance of training such patients to observe the minutiæ of catheter life, and of making the kidneys as active as possible before operation cannot be overestimated. Every prostatic operation should be preceded by a thorough general examination. The statistics of the results of prostatic operations demonstrate that the successful cases belong most frequently to the class having a small amount of residual urine and a moderate prostatic enlargement. An early diagnosis is most important. The choice of operation must depend upon the age, the resisting power of the patient, the size and shape of the prostate, with special reference to the seat and extent of the hypertrophy, and the condition of the kidneys and bladder. In the conduct of prostatotomy, as well as prostatectomy, the prime object is to avoid, as far as possible, the occurrence of shock, and to prevent the congestion of the kidneys by proper precautions during and by proper treatment after the operation.

Philadelphia Medical Journal, April 26, 1902.

Report of Several Cases of Corneal Complications in Conjunctivitis Due to the Koch-Weeks Bacillus.—Edward A. Shumway, from his experience with these cases, concludes that the Koch-Weeks bacillus conjunctivitis is apparently becoming more common in Philadelphia than has hitherto been observed. It may present itself in a particularly severe form, and be complicated by phylctenules and even by corneal ulceration. These cases are especially contagious, and extra precautions should be taken to prevent the spread of the affection, particularly among school children, As a rule, the disease is controlled by the use of mild astringent lotions, and applications of 2 per cent. solutions of nitrate of silver.

A Case of Diaphragmatic Hernia.—This case was under the care of W. Moser. The man had this hernia for some years and did not know how he got it. From his statement it appears to have originated simultaneously with a double inguinal hernia. He cannot recall any severe injury in the region of the diaphragm. It did not exist in childhood, as far as he can remember. The patient had no difficulty in replacing the mass, which probably contained a part of the stomach and intestines. Upon replacing the mass, several fingers could be easily passed through a large opening in the diaphragm, and a part of the heart could be easily grasped with the fingers. The writer thinks that cases of this character may be due to a slight traumatism or heavy lifting, and that a congenital, easily dilatable opening or malformation preëxists.

A Case of Adiposis Dolorosa.—John B. Roberts reports the case of a French woman, sixty years of age and a widow. She first menstruated after her marriage. She was menstruating a few weeks after her marriage when she heard of her husband's death. The flow stopped at once. Twelve years later she menstruated once again, at which time she heard of her mother's death. The flow ceased, and she has never menstruated since. She has never been pregnant. Nine years ago she broke the left fibula. According to her statement, the leg has always been abnormally large since that time. Gradually, both legs and thighs became very much enlarged by deposits of irregular nodular masses of fat. Constant pain was felt in the left leg from the time of injury. The extreme deposit of fat seemed to be limited to the lower extremities. Administration of thyroid extract and potassium iodide has been followed by marked diminution in size of the legs, and the pain has ceased. There are still large

[illegible]

The Lancet, April 12, 1902.

Diphtheria in the Newly Born.—G. A. [illegible] reports the case of a [illegible] days old, born after a normal labor. On the eighth day there appeared a [illegible] discharge from [illegible] nothing could be found to account for the condition. On the tenth day the discharge was increased [illegible] It was found that one month before confinement the mother had had a severe sore throat. It may have been diphtheria, and she herself may have been the source of the child's contagion. Author does not assent to the view that maternal milk possesses antitoxic properties. In this case the mother nursed the child throughout.

Pyrexia of Gastrointestinal Origin During the Puerperium.—Two cases illustrating the general fact mentioned in the title are reported by Ethel M. N. Williams. The author believes that the rôle of the intestinal tube in pyrexia during the puerperium is wider than is generally supposed. Cases both of septicæmia and pyæmia have been described in which the infecting organism has been found to be the bacillus communis, and it is much easier to suppose that the infection in these cases has taken place through the walls of the intestine rather than through a wound in the genital tract. It is known, as a matter of fact, that during the puerperium the resistance of the body against microbic invasion is very markedly diminished. It is but natural, then, to suppose that this loss of defensive power will be as apparent in invasion from the intestinal tube as in the more usual invasion from the genital tract. Obviously it is of the utmost importance to make an early distinction between these two classes of cases. In the gastroenteric cases, we should expect an absence of symptoms pointing to the genital organs, much flatulence and considerable abdominal pain, usually localized in the upper quadrants of the abdomen. A history of constipation is not always present, yet after the bowels have been acted upon, there is often evidence of a previous fecal retention.

On Cardiac Inadequacy.—Alexander Morison believes that some patients possess an abnormal smallness of the heart in proportion to the circulation it is called upon to maintain. This is a very important factor of success in treating those diseased conditions in which an additional strain falls on the organ. Certain cases of phthisis show an abnormally small heart. Physical examination may not suffice to reveal this abnormality, but in the x-ray we possess a most valuable diagnostic agent. When a heart essentially inadequate gives way under the strain of ordinary existence or exceptional effort, or in consequence of acquired impediment from disease affecting any portion of the circulatory system, the persistence, rapid onset, and intractability of the conditions induced may be expected to be characteristic of the essential and original fault. But, perhaps, the most delicate index to imperfect blood-pressure is the amount of the urine—that is, of water voided by the kidneys. The secretory structure proper to these organs may be healthy and the output of solids not apparently lessened, but the urine will have a high specific gravity and, proportionately, deposit a larger amount of solids. Such a condition may, of course, result and, as we know, does result, when a heart, however originally adequate, breaks down from any cause; but when such failure is supplemented by an essential inadequacy it may be expected to be a still more marked and, perhaps, more easily detectable sign. For the rest the essentially inadequate organ must participate in all the recognized phenomena indicating failure of the heart from any cause whatever.

The British Medical Journal, April 19, 1902.

The Seton in Migraine.—T. E. Watson gives his experience in a case of this kind. The patient was afflicted with obstinate migraine, the severe pain being almost constant, while insomnia added to his sufferings. He had no appetite, and was very thin and weak. After the introduction of a seton in the back of his neck, improvement was marked, and in three weeks he was almost well. The seton was then removed, and about ten days later he was perfectly cured. He has had no return of the pain since.

Notching the Soft Palate for Cure of Post-Nasal Obstruction in Adults.—J. M. Thomson describes this operation, which is very simple. The patient is anæsthetized, and the mouth held open by a gag; the palate is grasped with a [illegible] forceps, while with the scissors it is cut through on either side, a wedge-shaped piece being removed, this piece is half an inch high. There is then a good-sized notch to be seen in the middle of the soft palate. The post-nasal space can then be scraped if needed. After a few days' rest the patient can get up. In a week the wound has healed. The [illegible] loses much of its former [illegible] and sleep, which has been so [illegible] The author [illegible] that [illegible] which may come with [illegible] hay fever.

The Influence of Nasal and Nasopharyngeal Obstruction upon the Development of the Teeth and Palate.—A. L. Whitehead declares that it is quite evident that interference with nasal respiration is [illegible] and extensive deformities of the teeth and palate, and that, by the restoration of nasal breathing, the development of the maxilla can be [illegible] There are many cases of V-shaped deformity of the maxilla, with anterior protrusion due to other causes, but interference with nasal respiration is so common a cause that the condition of the nose and nasopharynx should be investigated in all these cases. Breathing exercises are undoubtedly valuable in some cases of nasopharyngeal obstruction produced by the presence of an abnormal quantity of adenoid tissue, especially if it is a first attack, or the repetition of a previous one with free nasal breathing in the interval. But when the obstruction is chronic, especially if acute exacerbations occur, when secondary aural affections exist, and when deformities of teeth and palate are present, it will be found that breathing exercises, unless preceded by operative measures, will be generally ineffective and valuable time will be lost.

Deutsche medicinische Wochenschrift, April 3, 1902.

Gunshot Wounds of the Skull.—Ernst v. Bergmann deprecates the routine employment of operative procedures in small gunshot wounds of the skull (those inflicted by shot 5, 6, 7, 8 and 9 mm. in diameter). He reports two cases to show that non-operative treatment is often followed by complete recovery even when symptoms of severe and extensive brain injury are present. In the first case there was an entire loss of consciousness and a complete hemiplegia of the injured side, except that the leg was somewhat less paralyzed than the arm. In many cases where an operation is performed the bullet is not located, and much harm is done by the necessary manipulation of the brain. Experience has also shown that the symptoms are not a sure guide to the location of the bullet, as it is frequently not found in the situation which such symptoms would indicate. The author believes that only those cases should be submitted to operation in which it can be definitely determined that the bullet lies near the cranial bones. In all other cases the best results are obtained by expectant treatment.

Surgical Treatment of Ascites Arising from Cirrhosis of the Liver.—Hermann Kümmell reviews the literature relative to this subject and reports seven cases which were operated upon following the principles laid down by Palma and Drummond. In the last case the length of time since the operation is too short for a correct estimation of the ultimate outcome. However, the liver and spleen have been markedly reduced in size, and the general condition of the patient is very good. The second and third cases died a few days after the operation; in both cases the general condition was very unfavorable, and the operation was only undertaken as a last resort. The fourth case died five weeks after the operation. During that time there was no recurrence of the ascites, although previous to the operation aspiration had been necessary six times within a shorter interval. There was no recurrence of the ascites in the first case for three years subsequent to the operation, and the general condition was good. At the end of that time the patient disappeared from view. In the fifth case there was no recurrence of the ascites for one year after the operation. Death then took place due to an intercurrent disease. The most striking result was obtained in the sixth case. Here the patient, when operated upon, was moribund. Recovery took place, and the patient has remained in good health until the present time. The operation took place on September 4, 1901. Kümmell thinks that it is very doubtful whether cirrhosis of the liver is to be cured by operation, but it is certain that, in most instances, the ascites and other annoying and dangerous symptoms may be permanently relieved thereby.

Münchener medicinische Wochenschrift, April 8, 1902.

Bone Marrow and Infectious Diseases.—Eugen Fraenkel has examined the bone marrow in certain infectious diseases in order to determine whether or not the specific microorganisms can be found therein. A case of typhoid fever showed the presence of typhoid bacilli in the spinal marrow. The diplococcus lanceolatus was found in the spinal marrow in five cases of pneumonia, but was not found in the marrow of the ribs. In two cases of facial erysipelas streptococci were found in the marrow, also the diphtheria bacillus in the spinal marrow in several cases of diphtheria. In a case of phlegmonous lesion of the forearm the staphylococcus pyogenes aureus was found in the spinal marrow. This microorganism was also obtained from the spinal marrow in a case of scarlet fever. Finally, streptococci and staphylococci were found in the spinal marrow in a case of tuberculosis. In all of these cases the vertebra showed pathological changes due to the presence of these organisms. These changes were chiefly of a necrotic nature. A more detailed consideration of them is reserved for a subsequent communication.

Changes in Color of the Hair.—W. G. Weinberg says that although the falling out of the hair is a well known and common result of syphilitic infection, the fact that the newly-formed hair which replaces that lost may be of a different color, has not been as yet reported. Three cases are described in illustration of such a change of color. The first was that of a woman who previous to the contraction of syphilis had black hair. As the result of this disease the hair came out in large quantities. When new hair grew in, it was of a dark blond color and so remained. The second case was in the husband of the first patient. Previous to syphilitic infection his hair was light. The new hair which replaced that which had fallen out as the result of this disease was of a dark color. The third patient had blond hair before he contracted syphilis, and the new grown hair was of a still lighter color. The cause of these changes of color of the hair is probably to be sought in trophoneurotic disturbances, which influence the amount of pigment in the hair bulb.

Stomach Washings with Nitrate of Silver Solutions; a Therapeutic and Diagnostic Cholagogue. — Franz Ehrlich gives the following technic as suitable for adoption in this mode of treatment: at first the fasting stomach is washed out with hot water (40° to 50° C.), which is continued until the water returns perfectly clear. There is then introduced ½ a litre of a 1 to 1,000 aqueous solution of silver nitrate at 40° to 50° C. This should remain in the stomach for ½ to 2 minutes. This latter process is repeated and the stomach is finally washed out with water until the return flow is absolutely clear. These washings are usually painless, but in nervous patients may cause some inconvenience. The diet should be that ordinarily given in chronic catarrh of the small intestine. The cases most suitable for this treatment are those of cholangitis or cholelithiasis complicated with cholangitis or cholecystitis. In such cases after one or more washings the liver markedly increases in size and may so remain for quite a long period. At times the enlargement of the liver is so great that a transient compression stenosis of the pylorus is produced thereby. Subsequently a painless, grass-green diarrhœa sets in which may be accompanied by the passage of gallstones. After a few days of such diarrhœa the liver decreases in size and the symptoms of the disease disappear. At times the swelling of the liver is so marked and continuous that the diarrhœa does not occur. When this is the case the washings with nitrate of silver should be frequently repeated. The effects produced by these washings are due to mechanical, thermic and chemical influences. At first both the intestinal mucus membrane and liver are irritated. The irritation of the former blocks up the intestinal orifice of the gall-duct and prevents the free passage of gall into the intestine. After a few days the irritation of this mucus membrane subsides but that of the liver continues. When this takes place the characteristic diarrhœa begins and the liver decreases in size. The washings should be repeated daily or at intervals of a few days each according to the indications in individual cases. Observations have shown that nitrate of silver given in medicinal doses by the stomach acts as a cholagogue. It is certain, however, that when thus given the results produced are not nearly so satisfactory as when the above described stomach washings are employed. This is shown by the following figures, gathered from a study of seventy-five cases: ordinary administration of nitrate of silver gave 25 per cent. cured without relapses, 37.5 per cent. cured with relapses, 37.5 per cent. not benefited. Stomach washings with nitrate of silver gave 63 per cent. cured without relapses, 31.8 per cent. cured with relapses, 4.5 per cent. not benefited. In only three of these seventy-five cases was it necessary to discontinue the treatment on account of the nervous disturbances produced. In the remaining seventy-two no disagreeable symptoms were produced. Five cases are described in detail in illustration of this method of treatment.

French and Italian Journals.

Tuberculosis of the Suprarenal Capsules in a Cow.—M. G. Petit describes these organs, which were taken from a cow which had suffered from generalized tuberculosis. Tuberculosis of the suprarenal capsules has been less frequently noted in animals than in men. While one of the capsules taken from this cow was perfectly normal, the other was ten times the normal size and was curiously changed. The surface was odular and irregularly infiltrated with caseous matter. It was also beginning to undergo calcareous degeneration.—*Bulletins et Mémoires de la Société Anatomique de Paris*, December, 1901.

Acute Hemorrhagic Encephalitis.—Erminio Masetti reports a case in which the finding of Fränkel's pneumococcus in the cerebral tissue, which was the seat of the disease, permits of the statement that the development of the acute encephalitis was due to the toxic infective action of the microorganism. The case was that of a man, previously in excellent health, who was attacked by a pleuro-pulmonary affection. Six days later he had a general convulsive attack of short duration, with loss of consciousness, involuntary emission of urine, and profuse sweating, followed by somnolence, and fatal coma. The pneumococci, after having caused the inflammatory conditions in the lungs, passed by means of the circulation to the brain, where they found the suitable conditions for the development of non-purulent hemorrhagic polyoencephalitis.—*Rivista Critica di Clinica Medica, March* 15, 29, 1902.

Radium.—Javal makes an interesting communication concerning the curious properties of the new metal, radium discovered and studied by Mr. and Mme. Currie. In the dark this metal emits a light which is peculiar to itself, which is not phosphorescence, and which is distinct from the Röntgen rays, although bearing a certain analogy to the latter. The rays from this metal traverse opaque bodies and produce physiological effects. Currie thinks that these properties could be utilized to discover if the optic nerve in the blind is absolutely atrophied, and if, accordingly, all hope should be abandoned of the recovery of sight. Javal cites several instances in which certain blind patients could perceive the glimmer of radium. In others, on the contrary, there was no perception of its light. This metal is still extremely rare. It is prepared in the form of the chloride.—*Gazette des Hôpitaux Civils et Militaires*, April 17, 1902.

Traumatic Diabetes.—Luigi D'Amato concludes from his studies of the subject that there is no macroscopic nor microscopic lesion of the nerve centers caused by the trauma and capable of explaining the appearance of the diabetes. In diabetes there may be fatty degeneration of the cerebral capillaries and small blood vessels, independent of arteriosclerosis and atheroma; degeneration of the walls may also cause a parietal fatty thrombosis. In addition to irregular degeneration of the nerve fibers in diabetes, there may be lesions of the nerve cells, which are also irregular. There may be a new form of atrophy of the liver, in which there is pigmentary atrophy of the gland cells, with increased interstitial tissue formed of cells and not of connective tissue. In traumatic diabetes there are lesions of the pancreas identical with those found in cases of diabetes from primary atrophy of the pancreas. He suggests therefore that traumatic diabetes may really be a pancreatic diabetes.—*Rivista Critica di Clinica Medica, March* 15, 22, 29, 1902.

Simultaneous and Independent Cancers of Both Lips.—H. Morestin reports this case. The patient was a man fifty-one years old. The mouth was affected with a general leucoplakia, covering the tongue, the cheeks, and the lips. No definite cause could be ascertained. The patient was a very moderate smoker, and was not addicted to the use of alcohol. He absolutely denied syphilis. The plaques were numerous, of a clear opaline appearance, with no point of great opacity. There was a pronounced tendency to ulceration. But of an entirely different aspect were two ulcerations, one on the left side of the upper lip, the other on the right half of the lower lip. The ulceration was seated on a very hard base, and the lip was infiltrated deeply into the muscular layer. In the submaxillary region on each side there was an enlarged ganglion. The general condition was excellent. There was no suffering. The rigidity of the lips hindered articulation and mastication to a certain extent. The diagnosis was confirmed by a microscopical examination. The writer removed both of the tumors, and the recovery was excellent, the healing being by primary intention. The result was satisfactory from all points of view. The only relation detected between the tumors was purely etiological—the diseased condition of the mouth.—*La Presse Médicale,* March 29, 1902.

Book Reviews.

Principles and Practice of Operative Dentistry. By John Sayre Marshall, M.D., Retired Surgeon, U. S. Army, President Army Examining Board for Dental Surgeons. Philadelphia and London: J. B. Lippincott Company, 1901.

This comprehensive volume begins with accurate descriptions of the anatomy, morphology and development of the human teeth, and much of its space is devoted to [illegible] [illegible] [illegible]. [illegible] [illegible] [illegible] [illegible] [illegible] the pathology of the teeth and much light has been thrown upon many pathological processes. The method and the actual use of dental dams are carefully gone into in this volume as a preliminary to describing those actual operations which are made necessary by [illegible] caries. The mechanical processes required for preparing cavities and the various instruments in use are very well illustrated and described by engravings and photographic reproductions. Detailed descriptions of filling materials, their preparation and relative advantages and disadvantages are likewise given. This is an important subject and deserves the considerable space given to it in this volume. Separately [illegible] of the teeth and neighboring parts belonging on the border line between dental and general surgery, on the [illegible] of the latter of which its treatment depends. Some of the finer mechanical processes required for such treatment receive in this work the attention which they deserve to make them valuable to the dentist. A number of chapters are devoted to the rarer diseases and injuries of the teeth, and these conclude a very satisfactory volume.

Some Thoughts on the Principles of Local Treatment in Diseases of the Upper Air Passages. 118 pages. By Sir Felix Semon, M.D., F.R.C.P. London and New York: The Macmillan Co., 1902.

This work consists of two lectures delivered in October last at the Medical Graduates' College and Polyclinic. They are in the main a protest against the prevalent "lust of operation." According to the author operative treatment of the upper air tract is resorted to in numberless instances where it is unnecessary, and operations of unquestionable value in really suitable cases are discredited by being performed wholesale. The author lays down in a broad manner the conditions requiring operative intervention and clearly discriminates in the matter of indications and contraindications, referring to the operations commonly done. His own conspicuous success as an operator has not blinded his judgment, and his statements are clear and trenchant. It will do every rhinologist and laryngologist good to read these lectures, by the delivery of which Dr. Semon has rendered a distinct benefit to this special field of medicine.

Municipal Engineering and Sanitation. By M. N. Baker, C.E. New York: The Macmillan Company, 1902.

This book is intended for that large and rapidly growing class of persons who either as officials or citizens are striving to improve municipal conditions, and gives a brief review of the whole field of municipal engineering, sanitation and economics. In its character, the book is essentially suggestive, and the physician will, as a citizen and taxpayer, find much food for thought within its covers. The number and variety of the subjects treated, their practical importance and the comparative newness of some of the topics discussed give special value to the book, which deserves a wide circulation among the general public. The efforts of the author seem to have been devoted to stimulating an interest in the various questions of municipal administration, of which those relating to sanitation are not the least important, and in this respect the volume will undoubtedly prove very successful. The book is not a practical sanitary guide, nor is it intended to be, but it indicates the main principles with which the municipal engineer should be conversant, without [illegible] [illegible] the study of these principles in detail.

Cats: How to Care for Them in Health and Treat Them When Ill. By Edith K. Neel. Philadelphia: Boericke & Tafel, 1902.

The first part of this little book of fifty pages is devoted to the care of cats in health, to hygiene, and the administration of medicines; the second to the treatment of pussy's varied ills by homœopathic remedies. We are unable from personal experience to affirm or deny the efficacy of arnica, rhus tox., aconite, pulsatilla, sabina and china in the prevention of abortion from various causes, but we can give our unqualified approval of the author's prescription for diphtheria, namely, to kill the cat.

Short Talks with Young Mothers on the Management of Infants and Young Children. By Charles Gilmore Kerley, M.D., Instructor in Diseases of Children, New York Polyclinic Medical School and Hospital; Assistant Attending Physician, Babies' Hospital, New York; Physician-in-Chief, Out-Patient Department, Babies' Hospital; Member of the American Pediatric Society. New York and London: G. P. Putnam's Sons, 1901.

This is a very practical little guide for the care of infants as to the general care of the nursery, the regulation of feeding, clothing, bathing and airing, and what to do in an emergency, and it contains also a brief description of the ailments and [illegible] [illegible] from which the infant or young child commonly suffers. Little description is added and some regarding the nursing and [illegible] treatment, but the author very properly refrains from any mention of drugs and indeed specifically and solemnly warns against drug giving by mothers or nurses, and above all against the use of cough mixtures, soothing syrups, and other patent medicines. What he has to say on this subject, as well as on nursing, home environment, bathing, clothing and various other practical topics cannot be too strongly commended to the careful perusal of mothers, both old and young, who, if they would heed Dr. Kerley's warnings, might spare their children much suffering, if not actual disease and perhaps a ruined life.

Clinical Hematology. A Practical Guide to the Examination of the Blood, with Reference to Diagnosis. By John C. Da Costa, Jr., M.D., Assistant Demonstrator of Clinical Medicine, Jefferson Medical College, Hematologist to the German Hospital, etc. Containing 8 full-page colored plates, 3 charts, and 48 other illustrations. Philadelphia: P. Blakiston's Son & Co., 1901.

In no branch of medicine, perhaps, are more rapid advances being made than in the study of the blood and in the application of the discoveries resulting therefrom to the diagnosis, prognosis and therapy of disease. It is, indeed, impossible to keep up with the progress of this fascinating study, except in the periodical literature, and even of the progressive weekly journals there is scarcely an issue in which the hematologist does not find some new fact, or at least theory, recorded. This, however, does not detract from the value of systematic treatises, like the one before us, for it is only in such that the beginner can find the information necessary to initiate him into the science, or the advanced worker can refresh his memory or find recorded some fact which would otherwise be hidden in all the voluminous periodical literature of the day. Dr. Da Costa has well met these requirements in this excellent work. He writes with the ardor of an enthusiast, tempered by the caution of an expert. The first section contains full and very clearly expressed directions for conducting blood examinations; the second treats of the blood as a whole, its composition and physical character and its morbid modifications—anæmia, plethora, anhydræmia, oligæmia, etc.; section third deals with hæmoglobin, the red cells, plasma, and blood plates; and section fourth with the leucocytes. In the fifth section the author takes up the essential diseases of the blood—chlorosis, pernicious anæmia, leukæmia, etc., devoting the sixth to a special consideration of the anæmias of infancy and childhood. The final section treats of general hæmatology—that is to say, the changes occurring in the blood during the course of general diseases and the deductions to be drawn from a study and comparison of the conditions found. The book, we are told in the preface, is designed as a practical guide to the examination of the blood by methods adapted to routine clinical work. We can only say that the author has succeeded in the task he set before himself, and no one can go far wrong who follows so capable a guide.

Essai de Sémiologie Urinaire, Etc., par Camille Vieillard. Préface par Albert Robin. Paris: Société d'Editions Scientifiques, 1902.

The book is divided into three parts: the system of urinary semeiology, general semeiology and applied semeiology. In the first part, after a short introduction emphasizing the value and importance of urine examination, the author points out the relation of the urine to the general condition of the organism, and in special to the organs most active in its formation, liver and kidney. From this standpoint he divides the indications of urinary analysis into two groups, the direct and redirect. The direct indications depend on the general status of nutrition, and on the functional integrity of the organs specially engaged in its formation. The redirect indications are given by conditions which secondarily affect the composition of the urine. This is followed by a discussion of the physiological processes which modify the character of the urine, food, drink, etc., physical and mental exercise; and, finally, by methods which the author recommends for the proper tabulation and recording of the results of analyses. The second part, which is devoted to general semiology, presents the conditions which will produce deviations from the usual values of the urinary constituents, *i. e.* the pathological variations in amount, color, appearance, etc., and their causes. This includes glycosuria, albuminuria and the sediments.

The third and last part considers such variations as occur in individual diseases, or specific groups of pathological processes: fevers, disorders of nutrition, diabetes, gout, etc., and the influence of primary diseases of the genitourinary tract. In a concluding chapter the author reviews once more all evidence which may be obtained from urine examination as being indicative of (1) general disturbances of nutrition; (2) of anatomical and functional changes of the kidney, and (3) of changes in the other parts of the genitourinary tract. In an appendix we find a description of some of the physical phenomena of urine, which has received a good deal of attention of late, *viz.*, the relationship of the freezing point to the molecular concentration of the urine, and its application to clinical problems, especially diagnosis and prognosis.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Sixteenth session, held at Washington, D.C., April 30, May 1 and 2, 1901. Vol. XVI. 730 pages. Philadelphia: Printed for the Association by Dornan, Printer, 701–709 Arch street, 1901.

THIS volume consists of fifty-six articles on various subjects, the majority of which will be read with much interest by general practitioners and advanced workers. They have a peculiar value in that they represent the work of those well qualified to speak on the subjects treated, and in the fact that they were specially selected for presentation to a discriminating audience.

It would take too long to review the many articles in detail, suffice it to say that they reach an unusual level of excellence. The work is well edited and printed, and contains several explanatory diagrams and a few plates, some of the latter in colors.

NEUROLOGICAL TECHNIQUE. By IRVING HARDESTY, Ph.D. The University of Chicago Press.

THIS little book of 150 pages admirably fulfils its purpose "to serve as an introduction and laboratory guide to the study of the architecture of the nervous system." The general introduction is taken-up with a discussion of the various fixation agencies, and instructions for the removal and handling of tissues that are to be examined. The various methods of staining are then taken up in sufficient detail.

A few paragraphs are devoted to formalin for purposes of dissection, and to a laboratory outline for the dissection of the central nervous system. The appendix contains the anatomical nomenclature for the nervous system and the sense organs. We are disappointed in not finding amongst the methods of staining one of the most useful and widely applicable, *viz.*, Van Giesen's. The book is a safe and useful guide for the beginner and for the advanced student.

THE ACCESSORY SINUSES OF THE NOSE; THEIR SURGICAL ANATOMY, AND THE DIAGNOSIS AND TREATMENT OF THEIR INFLAMMATORY AFFECTIONS. By A. LOGAN TURNER, M.D., Edinburgh, Surgeon for Diseases of the Ear and Throat, Deaconess Hospital, Edinburgh, with forty plates and eighty-one figures. 211 pages. New York: Longmans Green & Co., 1902.

THIS volume is made up of the elaboration of several lectures and papers previously published by the author, together with the results of additional observations upon the anatomy of the sinuses and their communications with each other and with the nasal chambers. Turner has had unusual facilities in the study of anatomical material, and brings, in addition to his work, the results of an extensive clinical experience. The book, therefore, becomes practically an atlas of the special topic of sinus disease and an exposition of the modes of treatment that have come to be recognized as the best. The plates are clear, the type excellent, and the index complete. But a leading feature is to be found, we believe, in the careful and painstaking anatomical studies that are the foundation of the work. Such knowledge, the author maintains, is essential for a proper understanding of the various symptoms connected with sinus suppuration. The anatomical variations in this region are many, and we cannot have too many studies in this direction. Such knowledge, coupled with a notable improvement in methods of examination, has brought about increased precision in diagnosis, and has consequently placed treatment upon a more rational basis.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 17, 1902.

V. P. GIBNEY, M.D., Vice-President, in the Chair.

The Symptoms and Course of Smallpox.—Dr S. DANA HUBBARD presented this paper. He said that the lesions on the mucous membranes were seen for the most part on those portions exposed to the air, but in severe cases they might be found throughout the mucous tracts. The varieties of smallpox were discrete, confluent and hemorrhagic or malignant. It was convenient for clinical purposes to speak of the different types as very mild, mild and severe. The term varioloid, being a misnomer, should be discarded, and in its place should be used such designations as mild and discrete. The period of incubation was from twelve to fourteen days, and the period of invasion about three days. There was nothing distinctive about the backache of smallpox. The eruption first makes its appearance on the forehead, at the hair line, and extends down behind the ears and on the back of the neck to the body. The best place to observe the rash for diagnostic purposes was upon the back, where the lesions were less apt to be obscured by scratching. When it first appears the eruption consists of small, round, oval, intensely red macules, one-eighth to one-quarter of an inch in diameter, which seem to be in the skin. These spots readily disappear on pressure or tension. Within twenty-four hours the macule changes to a papule, which is characterized by a peculiarly hard, shot-like feel. Later on the papule becomes a vesicle, and about the sixth day this is converted into a pustule. In from one to three days the umbilicated appearance is lost. It is during the stage of pustulation that the constitutional symptoms become more severe. About the eighth day the pustules reach maturity. About the ninth or tenth day a small dark spot appears in the pustule, and this gradually extends until the pustule dries up. Pustules do not rupture spontaneously and discharge their contents.

The complications of smallpox were usually ulcers, opacities, boils, laryngitis, zoster, sciatica, nephritis and gastritis. The hemorrhagic form is most malignant, and runs its course quite rapidly. Hemorrhage usually occurs as the lesions change from vesicles to pustules. Occasionally the eruption of malignant smallpox closely resembles that of scarlet fever.

The Diagnostic Features.—Dr. S. POLLITZER took up this topic. He said that the recognition of a case of smallpox might be simple, difficult or impossible. The diagnosis was difficult in atypical and complicated cases. It was impossible in most cases in the pre-eruptive stage. During an epidemic of smallpox, if a person presented the initial symptoms of smallpox, that disease might be suspected, even before the appearance of the rash. The characteristic eruption was sometimes preceded by a scarlatiniform eruption, and under these circumstances it might be distinguished from scarlet fever by the absence of angina and the strawberry tongue, and from measles by the absence of catarrhal symptoms. In cerebrospinal meningitis the difficulties of diagnosis were often very great. The rash of this disease, however, usually develops in successive crops, and is irregularly distributed. An attack of grip might simulate closely the early symptoms of smallpox, though in grip the muscular pains were more general, and symptoms referable to the respiraory tract quickly develop. The differential diagnosis between the backache of smallpox and lumbago could be readily made by the fact that lumbago is an afebrile disorder.

Upon the appearance of the rash, smallpox was most likely to be confounded with measles and varicella. The early papular eruption of measles bore considerable resemblance to the early stage of the smallpox eruption. The rapid defervescence observed in smallpox on the appearance of the eruption was in marked contrast with the increasing fever noted in connection with the development of the eruption of smallpox. The thin vesicles of varicella dried up from the surface, as it were, without pitting, and the comparatively [illegible] of the [illegible] vesicle is striking. The vesicle of varicella can be more easily ruptured, and its contents discharged, than in smallpox. In varicella the palms and the soles, except in [illegible], were affected, whereas in smallpox these regions are very rarely exempt. The only exceptions are in cases of smallpox of a very mild type. It might be laid down as a safe rule that a case [illegible] and [illegible] not smallpox if the patient had [illegible] fever. Herpes zoster was readily distinguished by the special grouping and location, and by the accompanying severe neuralgic pain, though occasionally pustules are found irregularly scattered over the body surface. The occurrence of fever in zoster also tended to obscure the diagnosis.

In general, drug eruptions could be distinguished by the absence of fever and of the usual symptoms of smallpox. The erythematous and purpuric eruption of iodism might be confounded with the hemorrhagic eruption of smallpox. Of all the diseases of the skin the pustular syphilide most resembled the lesions of smallpox. The lesions may be absolutely indistinguishable from those of smallpox by the appearance alone. The differential diagnosis could only be made by the closest inquiry into the history and a most careful observation of the illness. A pustular syphilide might be associated with a febrile movement. Other syphilitic lesions were sometimes present to give a clue to the correct diagnosis. In exceptionally obscure cases, vaccination should be practised, for although a negative result from the vaccination would have no value, a positive result would be of the utmost importance, and it could be obtained after a delay of only a very few days.

Dr. Pollitzer exhibited some lantern slides of smallpox cases.

Treatment.—Dr. GEORGE H. FOX read this paper, illustrating it with lantern slides. He said that no remedy or plan of treatment would apply to all cases of smallpox. The very mild cases hardly demanded any treatment. Mild cases sometimes occurred among the unvaccinated. He had noted a few such cases in connection with the present epidemic in New York city. In the malignant cases medical treatment also seemed unnecessary, because experience had shown that in spite of all treatment they quickly terminated fatally.

Vaccination After Exposure.—Some writers contended that vaccination, done after exposure to smallpox, had no effect on the disease which subsequently developed. The question was a difficult one to settle even after the observation of a large number of cases. It was the opinion of many good authorities that the vaccination began to exert its protective power at the time of the development of the vesicle, or on the eighth day, and as the period of incubation was usually twelve days, vaccination should be done. As the protective effect of vaccination was secured somewhat more quickly from humanized virus, it was desirable to use this when possible and to make several insertions.

As soon as the diagnosis of smallpox had been made the patient should be placed in a room devoid of unnecessary furniture, and the temperature of the room should be kept at from 60 to 65° F. If the disease were mild a daily bath should be taken, or if this could not be done, a cool sponge bath would usually be beneficial. In unvaccinated persons in whom there was reason to expect a severe attack the beard and hair should be closely clipped. In view of the recent advances in antitoxin medication it was possible that in the near future some specific for smallpox might be discovered. For the [illegible] cold applications were useful, but mustard plasters should be avoided, since the resulting irritation was liable to increase the pustules and add to the subsequent discomfort of the patient. The theory that the eruption could be lessened by [illegible] the [illegible] of the [illegible] on other parts of the body had never been confirmed in practice. If there was extreme nausea, vomiting, and thirst, the patient should be given small pieces of ice to suck. During the papular and vesicular stages little or no internal medication was required. A light diet should be ordered throughout the disease.

Local Treatment.—The local treatment of the eruption during the papular and vesicular stages had been a subject of experimentation and controversy. Most of the local applications, however, had generally proved to be more uncomfortable than beneficial. One continental observer claimed that the use of a mixture of sulphur and spirit, if applied in the papular stage, would prevent pustulation and hence much of the consequent disturbance.

Effect of Light.—It had long been thought that light had much to do with the severity of the eruption. The investigations of Finsen, Unna, and others showed that it was not the heat of the sun but the violet rays that caused pigmentation of the skin, and Finsen had suggested that it was only necessary to eliminate the chemical rays of sunlight by the use of red windows or curtains to mitigate the severity of the smallpox eruption. [illegible] and others had reported remarkably good results from this method, the patients passing directly from the vesicular to the stage of convalescence and no pitting resulting. The speaker said that his own experience with this method was limited to a few cases treated at the Riverside Hospital in 1893. One ward was fitted with red glass windows. The cases were of a mild type and the experiment was negative in its results.

Stage of Suppuration.—In the stage of suppuration the swelling of the face, hands and feet caused much suffering. A very nutritious diet which could be readily swallowed must now be given. Alcoholic stimulants were usually of the greatest service in this stage, and should be given freely, especially at night and in the early morning hours, when the vital powers are at the lowest point. Rectal alimentation was sometimes a valuable adjunct.

Pitting.—A host of local applications to the eruption in the suppurating stage had been recommended. The ointments, plasters, paints and varnishes which had been advised were unpleasant and rarely accomplished any good. At this stage it was too late to do anything to prevent pitting, though the disfigurement would be reduced to a minimum by all local measures which tended to reduce the intensity of inflammation. The best antiphlogistic application to the skin of a smallpox patient was lint soaked with cold water containing a little glycerin, and this should be covered with rubber tissue. It might be necessary to immerse the hands and feet in tubs of cold water—indeed, if the patient were put in a [illegible] condition he might with benefit be immersed for hours in a bath as recommended by Hebra. For the softening of the crusts and allaying the itching [illegible] the best [illegible] was a [illegible] solution of carbolic acid. Still greater relief would be afforded by frequently spraying the parts with carbolized water or with chloroform containing some antiseptic. Before discharging the patient he should not only have a bath but should have the head shampooed with carbolic soap, the nails should be clipped and the mucous surfaces of the body disinfected with peroxide of hydrogen. The hard kernels or "seeds" left imbedded in the more horny parts of the integument must be dug out before the patient is allowed to mingle with other well persons.

Diagnosis of Unusual Cases.—Dr. DILLINGHAM said that a good deal had been said this evening about the typical cases of smallpox, but a physician should have no difficulty in diagnosticating such. The period of incubation was usually from twelve to fourteen days, but it was often longer. He recalled one case in which it was seventeen days, and mentioned the fact that cases had been reported in which this period was twenty-one days. The period of invasion was said to be three days, and while this was ordinarily the case there were many cases in which there was no period of invasion, the first thing noticed being the eruption. It was sometimes stated that papules, pustules and vesicles do not appear at the same time in the same area, yet he had met with a number of cases in which these different stages were all visible at one time. Lesions were not always present in the throat, but, if present, this was one of the first places in which the eruption was visible. With regard to the diagnosis between scarlet fever and hemorrhagic smallpox, there was one point of great value, *i. e.* that if there were hemorrhages in the conjunctiva scarlet fever could be ruled out. Moreover, the eruption in hemorrhagic smallpox was of a deeper hue than the eruption of scarlet fever. The early eruption of smallpox, that preceding the papular eruption, usually appeared first in the groin and then in the axilla, and not upon the body, thus affording a useful means of differentiating it from measles and scarlet fever. He had seen vesicles just as superficial in smallpox as in varicella, though this was not the rule. He had seen several cases of smallpox in which the first lesions were vesicular. There was a large number of cases of smallpox, and severe ones, too, in which there were no lesions in the palms. In making the diagnosis between smallpox and varicella there was no single lesion which could be implicitly relied on. As far as prodromal symptoms were concerned, he had seen as severe prodromal symptoms in chickenpox as in smallpox, though, of course, these symptoms did not last so long as in smallpox. The lesions of smallpox might not go to the papular stage, but dry up and abort. There was a class of cases in which hemorrhage took place into the vesicles, and then the lesions aborted. These cases were not severe ones. He had seen cases of smallpox in which the first lesions had been upon the body instead of upon the face.

Vaccination After Exposure Does Protect.—If the patient were vaccinated at the time of the exposure and the vaccination were successful, that person would not have smallpox. If the person were vaccinated several days after the exposure, the smallpox would be modified. If there was a well developed areola before the outbreak of smallpox, the latter disease would be decidedly modified by the vaccination.

Preventive Serum Treatment.—Dr. J. H. HUDDLESTON said that it had been shown that immunity to smallpox could be given to animals by the injection into the animal of an amount of serum, collected two weeks after vaccination, equal to half of the weight of the animal. It was because of the enormous size of the dose that this method had not been employed in the human subject to any extent for the prevention of smallpox. The risks and inconvenience of injecting a pound and a half of serum were evident. Moreover, in a few instances in which this serum treatment had been tried the results had been disappointing.

Laboratory Diagnosis of Smallpox.—The difficulties of diagnosis had been clearly brought out by the previous speakers, but nothing had been said about the aid that might be rendered by the laboratory. One authority on blood examination had declared that the blood picture in smallpox was characteristic, and afforded an important aid in the differential diagnosis of this disease. This picture consisted in a lymphocytosis and of a certain number of abnormal white corpuscles. It was not claimed, however, that it would distinguish between smallpox and chickenpox. The speaker said that, along with Dr. Braunlich, he had endeavored to confirm this statement regarding the value of blood examinations, but had found that the blood picture could not be depended upon as a diagnostic aid.

It had been demonstrated that monkeys are susceptible to vaccinia and to variola, and to Dr. W. H. Park was due the credit of suggesting that, by the inoculation of monkeys, it was possible to determine at the outset the character of a suspicious epidemic. This process of testing was slow and expensive, but the results were positive, and of great value, not in the individual case, but in promptly determining the nature of an epidemic. It was quite possible that this method could be so perfected that serum could be taken from lesions of the suspected cases and forwarded in tubes to a laboratory for inoculation into monkeys.

Vaccination After Exposure.—Dr. Fox said that Dr. Welch of Philadelphia had reported 194 cases of vaccination performed during the stage of incubation. Of this number, 38 were perfectly protected from smallpox; 16 were almost protected; 31 were protected to a well marked degree; 30 were partially protected, and 79 were unprotected.

Dr. HUBBARD reported two cases that he had seen, in which, although a successful vaccination had been performed on the day of the exposure to smallpox, the vaccination had not served as a protection against smallpox.

Multiform Rashes in Smallpox.—Dr. POLLITZER expressed the opinion that it was absolutely impossible for a case of smallpox to show the lesions of all of the various stages of that disease at one and the same time. If Dr. Dillingham had seen papules, vesicles and crusts at the same time, it must be that of some other disease, complicated with smallpox, and that these varied lesions were not all due to the smallpox.

Dr. HUBBARD said that it had been the experience of the diagnosticians of the health department that these multiform rashes are quite commonly observed in smallpox. He objected to the recommendation of Dr. Fox that the temperature of the room for a smallpox patient should be 60° to 65° F., on the ground that this distinctly favored the production of severe bronchitis and pneumonia .His own experience had been that, when the temperature of the ward was kept over 70°F., there was decidedly less pneumonia.

Congratulatory Telegram to Professor Leyden.—On motion of Dr. MAX EINHORN, the Academy of Medicine voted to send to Professor Leyden of Berlin a telegram, congratulating him on reaching his seventieth birthday on April 20.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held April 15, 1902.

E. E. SMITH, M. D., Chairman, Pro Tem.

Aids in Life Insurance Examinations.—Dr. ABBOTT SMITH PAYN was the author of this paper. He said that the opthalmoscope should always be used in every case involving a large amount of money. The laryngoscope was sometimes useful. The spirometer was applicable only to office work, and its value in life insurance work was doubtful. The same might be said regarding the sphygmograph. The aid of the clinical thermometer was worthy of further study and discussion. The value of the centrifuge was now well known, and this instrument was quite generally employed by insurance examiners. In many cases declined insurance because of râles in the lungs it would be a great advantage to resort to examination of the sputum. He had known of a case of pernicious anæmia having been passed by three companies and insurance granted for a large amount, though the disease was already far advanced and death took place within three years. This showed the need for blood examinations. The urine should, of course, be examined in every instance. While the pathology of true albuminuria was not yet well understood it might be said to be due to: (1) Disturbance of the circulation; (2) Changes in the blood composition, and (3) Changes in the epithelium of the kidney. Functional, accidental or spurious albuminuria and that to the admixture of semen, pus or blood with the urine. The mere finding of albumen in the urine, therefore, was only a clue for further study, and the microscope would satisfactorily decide the true significance of the albuminuria in the individual case.

The Significance of Glycosuria.—Dr. Warren Coleman presented this paper. He said that for clinical purposes the normal urine might be considered as free from sugar. The author considered the following varieties: (1) Alimentary; (2) Toxic; (3) Forms associated with diseases and injuries.

Alimentary Glycosuria.—The ingestion of cane sugar, grape sugar and milk sugar in quantities of 200 grm. caused a temporary glycosuria. The lactosuria observed sometimes in nursing women could be classed as alimentary glycosuria. It was rarely observed except when there was an interference with the secretion or outflow of the breast milk.

Toxic Glycosuria.—This form included those conditions of the urine following the ingestion of certain medicinal substances. In certain of these cases it was pretty certain that the reducing agent was not sugar. Among the medicinal substances giving a reducing reaction with Fehling's solution were chloral, chloroform, arsenic, turpentine and sulfonal. The glycosuria observed in those who had worked long in lead was believed to be due to the action of the lead on the renal cells.

Glycosuria Associated with Diseases and Injuries.—Transient glycosuria was often found in connection with cerebrospinal meningitis, Asiatic cholera, typhoid fever, typhus fever, tetanus, pneumonia and tuberculosis. It was sometimes observed after violent paroxysms of pertussis, and it was not uncommon in persons presenting the typical symptoms of interstitial nephritis. Transient glycosuria was well known to occur in connection with many nervous disorders. It was also observed as an accompaniment of cerebral hemorrhage, hemorrhage into the pons and spinal bulb, cerebral softening, cerebral tumors, disseminated cerebral sclerosis, injuries to the vertebral column, insanity, neuralgias generally, hysteria, mental emotion, and exophthalmic goiter. It had long been known that there was a form of glycosuria found in gouty persons, particularly in those having the suppressed form of gout. As a rule it yielded readily to dietetic treatment. Oftentimes the first indication of its existence was the discovery of sugar in the urine. Obesity and glycosuria were often associated. In many cases this form of glycosuria was undoubtedly of alimentary origin, but in others its origin was deeper and much more obscure. Diabetes rarely appeared in corpulent persons before the fortieth year and was usually mild in character and quite amenable to treatment.

Pancreatic Diabetes.—The association of diabetes mellitus with lesions of the pancreas was known to be more frequent than diabetes alone or pancreatic disease alone. Complete destruction of the pancreas in man might be assumed to cause diabetes, but of no special form. It had been proved that the symptoms supervening on removal of the pancreas were not due to loss of the pancreatic juice. The islands of Langerhans were supposed to form the internal secretion of the pancreas. It had been very recently asserted by one experimenter that the blood and lymph contain an agent which destroy sugar, and that this agent is contained in the white cells.

Adrenalin Glycosuria in its Relation to Human Diabetes.—Dr. C. A. Herter presented a paper on this subject. He said that adrenalin glycosuria possessed a significance much greater than that attaching to the mere fact of the occurrence of this form of glycosuria. About six months ago Dr. Blum had made some experiments in injecting the suprarenals of sheep into rabbits and dogs. He found that when large quantities of extract prepared by him from the adrenals of sheep were injected into these animals that they almost without exception developed glycosuria. At times this glycosuria was only slight, but in other instances it was considerable. The highest percentage observed was [illegible]. The quantity of extract used in these experiments was large, and almost always at the site of the injection there was some [illegible]. These observations had been repeated in Germany and in this country. The speaker said that, with Dr. Richards, he had repeated these experiments, using adrenalin chloride as prepared by Dr. Jokichi Takamine. He injected the adrenalin into the peritoneal cavity of dogs and found that [illegible] large quantities of sugar were always present in the urine, frequently as high as 8 or 10 per cent. The degree and the duration of the glycosuria were much influenced by the conditions of the experiment. For instance, if subcutaneous injections of adrenalin chloride were made in dogs weighing from fifteen to twenty-five pounds, the quantity of sugar in the urine would be small. If the same dose were given intravenously the amount of sugar would be much larger. If the adrenalin were administered by mouth there would be as a rule no sugar in the urine. For a short time after the intraperitoneal injection of the adrenalin the animal would remain quiet; then, after an interval of about fifteen minutes, the animal became wildly excited. This period of excitement ordinarily lasted half an hour or an hour, and was followed by a prostration lasting several hours. By the following day the animal would have resumed its normal appearance and behavior. The glycosuria lasted, as a rule, only a few hours, rarely more than twenty-four hours. The total amount of sugar excreted in the dog of medium size was not more than a few grammes, although the percentage of sugar might be ten or twelve.

Blood Sugar.—Dr. Herter said that his associate, Dr. Richards, had made some very careful experiments on the blood sugar. He had found that in these injections experiments the increase in the blood sugar might be very marked within a few minutes after the injection. It was interesting to note at the conclusion of the experiment there might be considerably less sugar than at the beginning, half the original quantity, or even less. In this respect it differed markedly from the glycosuria following the administration of phloridzin. The glycogen in the liver probably bore a very important relation to this particular variety of glycosuria. In dogs well stored with glycogen the largest glycosuria was observed; in dogs that had been starved there was very little glycosuria after the administration of adrenalin. The phloridzin diabetes was capable of being induced after the action of the adrenalin chloride had worn off.

An Acquired Tolerance to Adrenalin.—The effect of repeated injections of adrenalin was of no little interest. An attempt had been made to give dogs 5 to 10 c.c. of adrenalin chloride for a period of several months, giving it every day or every other day. As a rule the quantity of sugar diminished quite rapidly. Two of the dogs died in a month or two from over-doses of adrenalin, but two others were now alive after a period of three months. The last few doses given had failed to cause any glycosuria, from which it seemed probable that some sort of tolerance to the adrenalin had been established. How far this action was due to tolerance and how far to a species of immunity, Dr. Herter said, he was not yet prepared to say. These dogs lost their appetite and became very thin, so that probably very little sugar was stored in the liver and in the muscles. It was known that under these conditions the adrenalin would not produce glycosuria. Both of these dogs, after this immunity had been established, were well fed for a week or two, and then on resuming the administration of the adrenalin large quantities of sugar appeared in the urine—as much as in the first instance.

Fatal Doses of Adrenalin Chloride.—If a dog weighing about fourteen pounds were given an injection of 10 c.c. of adrenalin chloride into the abdominal cavity, the animal would almost surely die within twenty-four hours. It would first become excited, then prostrated; then there would be frequent vomiting and bloody diarrhœa. The autopsy in such cases showed the pancreas to be the seat of hemorrhagic changes, and the intestinal canal was often intensely congested throughout its whole extent. In certain parts of the intestinal tract the epithelium had been completely stripped off. The pancreas showed numerous focal necroses and hemorrhages. In some cases the acini had suffered more than the islands of Langerhans, while in others the reverse had occurred. Apparently these changes in the pancreas bore no definite relation to the glycosuria. It had been found that glycosuria might occur entirely independently of any visible change in the structure of the pancreas. If a dog were opened, and a bit of the splenic end of the pancreas nipped off, it could be hardened and studied histologically. If then the dose of adrenalin were given intravenously and a marked glycosuria were produced, another piece of the pancreas, contiguous to the portion already examined, could be removed and examined. In three instances in which such an examination had been made at the height of the glycosuria, it had been found impossible to distinguish between the first and second pieces of pancreas removed.

Pancreas Responsible for the Adrenalin Glycosuria.—In order to determine whether these experimental glycosurias were dependent upon direct contact of the adrenalin with the pancreas, Dr. Herter exposed the pancreas and applied the adrenalin chloride with a brush. It was found that when about 1 cc. was applied to the surface of the pancreas in this way, a rather marked glycosuria occurred almost invariably. It was interesting to note that a quantity of adrenalin chloride, when applied directly to the pancreas, would provoke glycosuria, but would not excite glycosuria if applied to the spleen or to other parts of the body. It was, therefore, evident that the pancreas was the organ concerned in the production of this adrenalin glycosuria. When well-fed animals were given adrenalin at the height of digestion, the resulting glycosuria was much more marked than when the animals were poorly fed and the injection made at another time. It was not found necessary to apply the adrenalin to the entire surface of the pancreas in order to produce glycosuria; its application to a very small area would suffice for this purpose.

Mode of Action of the Adrenalin.—Naturally the first thought would be that the production of the glycosuria was connected with the well-known vasomotor action of the adrenalin. However, instead of finding blanching of the pancreas when the adrenalin was applied, it was noted that the pancreatic tissue became reddened. Again, when the adrenalin was injected intravenously, there was no visible change in the vascularity of the pancreas. Thinking that possibly the glycosuria might be dependent upon the general rise in blood pressure induced by the adrenalin, the experiment was made of injecting into the peritoneal cavity 5 cc. each of spirits of glonoin U. S. P. and adrenalin chloride. The glonoin was used to offset the blood-pressure-raising action of the adrenalin, and it was found that this did not in any way interfere with the production of the glycosuria; hence, it was evident that the adrenalin did not cause the glycosuria by its action on the bloodvessels.

Oxidizing Function of Pancreas and Glycosuria.—Continuing, Dr. Herter said that he had next experimented with cyanide of potassium, which is known to produce glycosuria. If one or two cubic centimeters of a one-thousandth normal solution of cyanide of potassium were applied to the pancreas, glycosuria would occur within a few minutes. Some years ago it had been shown by Geppert that, in cyanide poisoning, the blood contains a very small quantity of carbon dioxide, while the quantity of oxygen in both the venous and arterial blood is decidedly increased. This investigation reached the conclusion that the cells of the organism were no longer able to take up oxygen. Dr. Herter said it had occurred to him that the adrenalin glycosuria might be due to the fact that the pancreas had been deprived of its ability to take up oxygen. The reddening of the pancreas seemed to favor this view. The next step in the investigation was to make use of a number of reducing agents, such as ammonium sulphide and sulphuric acid. If carbon monoxide were permitted to flow against the surface of the pancreas, taking care to keep the pancreas under normal conditions, a certain amount of the carbon monoxide was taken up and converted into carbonic dioxide, and glycosuria results. Benzyl alcohol had also been tried, because it is a powerful reducing agent, and does not injure the pancreas. Its application was followed by a marked glycosuria, and the same was true of pyrogallol.

Adrenalin a Powerful Reducing Agent.—The adrenalin chloride was oxidized with various substances, such as permanganate of potassium, chlorine, sodium nitrite and bichromate of potassium. The oxidation with chlorine was perhaps the most satisfactory in depriving the adrenalin of its reducing power. There could be no doubt that the glycosuria following the administration of adrenalin was intimately connected with its reducing action. It was known that the adrenal glands contain substances allied to pyridine. It was found that pyridine gave rise to only a little glycosuria, while piperadine caused an exceedingly marked glycosuria. Oxidizing, as well as reducing, agents had been employed upon the pancreas as controls.

Conclusions.—Dr. Herter said he thought he was justified in making the assertion that interference with the oxidizing function of the pancreas was the explanation of all the forms of glycosuria that he had been considering. From the foregoing facts it was reasonable to believe that in studying the production of glycosuria, one must take into account the existence of reducing substances in the blood in proportion to the oxidative capacity of the pancreas. It was probable also that the structural changes observed by Opie in the islands of Langerhans were secondary. In conclusion, the speaker expressed the hope that this special method of investigation that he had employed in this research, *i. e.* local applications to particular groups of cells, might be used with profit in studying the activities of other organs, as for example, the kidneys.

Dr S. J Meltzer called attention to certain discrepancies in the results obtained by Dr. Herter and the three other observers who had investigated this subject. The three others had made use of an aqueous solution of the suprarenal, while Dr. Herter had used exclusively adrenal in chloride. He thought it was possible that there was in the suprarenal two different substances, one substance which was injured or decomposed on exposure to heat, and another, which is found in adrenalin, and which is capable of exciting glycosuria. The speaker then commented upon the fact that glycosuria would not occur in the experimental removal of the pancreas so long as a small portion of this organ was allowed to remain, while according to Dr. Herter's experiments, glycosuria was produced even when a very small portion only of the pancreas was painted with adrenalin. The contrast was so sharp in these two sets of experiments that he was inclined to think that the glycosuria produced in those two cases was not the same. It was also possible that the glycosuria was a result of reflex action from the application of the adrenalin to the pancreas.

Dr. Graham Lusk said that, after sifting carefully all of the evidence at our disposal, one arrived, by a process of exclusion, at the conclusion that the pancreas alone is concerned in the development of glycosuria.

Dr. Herter closed the discussion. He said, with regard to the diastatic ferments that Dr. Crofton had found in the suprarenal gland, that he did not look upon this as of much importance, because there were few parenchyma-

[illegible] that did not contain a diastatic ferment to some amount. However, Dr. Crofton stated that the strength of this ferment was greater than in other glands, with perhaps the exception of the pancreas. Dr. Herter said that he had not found it to doubt the correctness of the observations made by Dr. Crofton, but he did not consider the diastatic ferment necessary to the explanation of the glycosuria. It was possible to boil the adrenalin solution for five minutes and inject it peritoneally, and obtain about the same effect as was observed when it was used without having been boiled. It was well known that very few ferments would stand such a degree of heat, and certainly all of the known diastatic ferments were destroyed by that temperature. Dr. Crofton had recently made a statement that he had been able to produce glycosuria after having boiled his own suprarenal extract. It could not be denied that there were discrepancies in the results of the different observers, but it should be noted that he had worked with much smaller quantities than had the other three investigators.

NEW YORK ACADEMY OF MEDICINE

SECTION ON SURGERY.

Stated Meeting, Held April 14, 1902

JOHN B. WALKER, M.D., Chairman.

Suture of Recurrent Fracture of Patella.—Dr. CHARLES A. ELSBERG presented a man who had fractured his patella, for the first time, about two years ago. With the aid of a knee-cap, he had been able to walk around fairly well, but one year later he had again fractured this same patella. After a delay of some months, the man came under Dr. Elsberg's observation, and was operated upon. A very large amount of fibrous tissue was found between the two ununited fragments. This was removed, and the fragments sutured with chromicized catgut. The wound healed by primary union, and he was walking around in about six weeks. Since that time the function of the limb had been perfect.

Adenolipomatose Symetrique.—Dr. ELSBERG also presented a man about fifty years of age, a patient in the Montefiore Hospital. About eight monshs ago a number of tumors developed in the front of the neck, on either side, and in the lower cervical region. These growths would grow rapidly for several weeks, and then stop growing or decrease in size. One of them had been excised, and had been found to consist chiefly of fatty tissue, but there was also considerable lymphomatous tissue present. This was a very rare condition, which had been described by the French under the name of *adénolipomatose symétrique*. The disease appeared to be confined to the male sex, and its victims were very liable to develop tuberculosis—indeed, this patient had contracted tuberculosis while under observation.

A Case of Inoculation Tuberculosis.—Dr. M. W. WARE presented a little boy who had stepped upon some sharp object, thus receiving a wound which showed no disposition to heal. After three weeks it was evident that the wound was infected with tuberculosis. The patient disappeared from observation for a short time, and on his return it was found that the glands of the inguinal region on the same side as the plantar wound had become infected. This occurred four weeks after the original injury. There was no history and no evidence of the child's having had tuberculosis before the injury to the foot. The speaker said that he had seen several cases of inoculation tuberculosis, and all of them had been very virulent forms of tuberculosis. One case was a tuberculous ulcer following piercing of the ears, and it was supposed that the thread passed through the ear had been moistened with the spittle from a tuberculous person. In another case a man became infected by being struck with a cuspidor in a barroom fight. Most of these infections had made themselves evident within four weeks after the injury.

Resection of Transverse Colon for Intraintestinal Tumor.—Dr. WILLY MEYER presented a woman of twenty years who had come under his care last summer. In November last, she had been suddenly seized with abdominal colicky pain and vomiting. Soon afterward a movable tumor had been noticed in the abdomen, situated sometimes to one side and sometimes to the other side of the median line. When on the left side the pains were more intense. On examination he had found a movable tumor which puzzled him. After keeping her under observation, it was concluded that the tumor was omental. Finally, an exploratory incision was made, and at the mesocolic attachment the tumor was found to be sessile. There were many enlarged glands in the vicinity, which seemed to point to the diagnosis of sarcoma of the colon. The colon was clamped and the gut resected and sutured. The patient made an uninterrupted recovery, and since then had felt entirely well. The pathologist's examination showed the tumor to be a lipoma.

Round-Cell Sarcoma Causing Intussusception.—Dr. MEYER referred to another case, that of a boy who had been sick with all the symptoms of chronic stenosis of the intestine. On examination a tumor could be felt in the right iliac fossa. A diagnosis of chronic intussusception was made, and on operating, an intussusception of the ascending colon into the transverse colon was found. It was necessary to resect the colon from two inches above the vermiform appendix to the middle of the transverse colon. A Murphy button was used to unite the divided portions, and this button was passed on the eleventh day. Within the intussusception was found a round-cell sarcoma.

Successful Extensive Resection of the Bowel.—Dr. CHARLES H. PECK said that, on July 13, 1901, the woman, whom he was about to present, had been curetted by a physician for retained secundines, and during this operation the uterus was ruptured. The patient had come under his observation twenty-four hours later with evidence of peritonitis. She was at once operated upon, the recent adhesions being separated and the coils of intestine drawn out until the healthy portion was in sight. Extensive gangrene of the bowel was found. This was resected and a Murphy button inserted. Her condition was very critical for two or three days, but after that she did fairly well. A small fecal fistula appeared on the seventh day, but closed spontaneously in three days. An abscess formed behind the uterus, owing to imperfect drainage, but, after opening this, recovery was uneventful, and the patient was up and around in about four weeks. The resected portion was measured after the operation, and was found to be eight feet five and a half inches. This, Dr. Peck thought, was the largest portion of bowel that had been resected in this country. The patient's nutrition had remained excellent, and there had been no diarrhœa but she had a very vigorous appetite. The specimen was exhibited.

Dr. WILLY MEYER spoke of a case of inoculation tuberculosis occurring about four weeks after a ritual circumcision. This, like several other similar cases, had proved to be a very virulent infection, and had required very extensive excision of the lymph nodes in the vicinity.

Dr. M. W. WARE said that a search through the literature showed that in 80 per cent. of these cases of inoculation tuberculosis the disease develops in other parts of the body. In the case reported by him, microscopical examination of the diseased tissue had revealed a typical picture of tuberculosis. The patient had exhibited a remarkable intolerance to iodoform dressings. Although he had employed blunt dissection of the muscles, he had found that this method gave sufficient room for the removal of the diseased glands, but he could easily imagine that in some cases in which the glands were larger it would not be sufficient. Moreover, he had found that this method of dissection had given a wound which had not drained at all satisfactorily.

Rôle of the Bacillus Proteus Vulgaris in Surgery.—Dr. M. W. Ware, in this paper, reported a case of proteus infection, and gave a rapid review of the literature. He showed that cases of periostitis, osteomyelitis, empyema, peritonitis arising from the intestinal tract, gangrenous diphtheria, etc., sometimes arise from proteus infection. Attention was directed to the statement of Schnitzler that this bacillus is alone capable of causing cystitis, a contention that had been abundantly supported by other observers. The streptococcus was the most frequent companion of the proteus. It should be remembered that proteus infection usually originates in the intestinal tract.

Dr. E. Libman said that, from animal experiments that he had made, he was convinced that the proteus had a special predilection for causing very marked degeneration of the liver and kidneys. In these cases a special reaction had developed in the blood, showing that the proteus was really the infecting agent, and not merely a parasite. The proteus was most commonly found in general peritonitis, appendicitis, and chronic brain abscess due to disease of the ear. He agreed with the reader of the paper that it was probably a secondary infecting organism.

Infection by a Paracolon Bacillus Secondary to Typhoid Fever.—Dr. A. A. Berg was the author of this paper. He said that last August he had seen a man of thirty-three years, who ten days previously had had a sudden attack of nausea, vomiting and a feeling of marked weakness. The temperature was 100°F., and there was considerable abdominal distention. After a free movement of the bowels, the patient was decidedly better, but he remained in bed for two days. On the seventh day he had been again seized with intense pain in the epigastrium, occasionally radiating to the back. The next evening the temperature had risen to 103°F. and the pain was severe and typical of biliary colic. He was slightly jaundiced. When seen by the speaker his temperature was 104.6°F. in the rectum, and the pulse was 124. There was marked heaving of the precordium, and the heart was dilated. The free edge of the liver was not palpable. In the right hypochondrium could be felt a mass about the size of a large lemon. The diagnosis was thought to lie between empyema of the gall-bladder and abscess of the liver. Operation was advised, but the man did not enter the hospital until two days later. The leucocyte count was 15,000 and the Widal reaction was negative. Under chloroform anæsthesia, an exploratory incision was made. The surface of the liver was for the most part smooth, and the gall-bladder was moderately distended, but the contents of the gall-bladder could not be expressed into the common duct. No stones could be felt in the gall-bladder. Aspiration of the liver in many directions yielded no pus. The gall-bladder was aspirated and black bile withdrawn. After the operation the epigastric pain continued to be severe. The urine contained hyaline and granular casts. A few days later the liver was again aspirated with negative result. At this time the patient became delirious and apathetic. Three days later the leucocyte count was 10,000 and the Widal reaction was positive for the first time. The patient died of exhaustion. About six days before his death 11 cc. of blood was taken for a blood culture, and this yielded a microorganism like that which had been isolated from the gall-bladder. In the blood, urine and gall-bladder during life a paracolon bacillus was found. The autopsy was made under great difficulties. Healed and healing ulcers were found in the ileum. The conclusion of the pathologist was that the case was one originally of ambulatory typhoid, and that the paracolon infection was secondary. The speaker thought that the paracolon infection had probably excited a catarrhal inflammation of the gall-bladder.

Experiments with Cargile Membrane.—Dr. R. T. Morris presented a paper with this title. He said that he had received from Dr. Cargile of Arkansas, a particularly thin variety of goldbeater's skin, or the peritoneum of the ox, with the request that he try it as a means of preventing intestinal adhesions under the same conditions in which Senn's omental grafts were appropriate. Dr. Morris said that he had made a series of experiments with this membrane on twelve rabbits. It was found that where the bowel had been scarified and the membrane sutured over it that this membrane became intimately adherent to the bowel, and even when the surface of the gut had been infected, the infection was prevented by the membrane from spreading to the surrounding tissues. It was also found to completely prevent the formation of adhesions under the line of the abdominal incision when the conditions were such as would have surely led to extensive adhesions if the membrane had not been used. The rabbit on which this expeiment was made, was killed forty-five days after the operation, and it was found that the membrane had been absorbed. Experiments with chromicized membrane showed that the period of absorption was not materially modified. This membrane apparently allows moisture to pass through it, so that the tissues beneath do not become sodden. It was, therefore, a useful substance to place over the line of incision. If cemented down with collodion the wound would be closed and sealed without sutures, and the transparency of the membrane would allow of the surgeon's watching the wound. The membrane which he used had been sterilized by the use of cumol and heat.

Dr. A. A. Berg said that he had recently tried this membrane in a case of strangulation of the small intestine, in which the serosa had been completely stripped off in efforts to relieve the condition. He had covered this surface with the Cargile membrane and the patient had done extremely well.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Annual Meeting, Held April 21, 1902.

Parker Syms, M.D., President.

Dr. A. H. Goelet presented a number of specimens.

Ovarian Cyst Removed Intact.—This specimen had been removed from a woman of thirty-nine years, who had suffered for a number of years from recurrent attacks of pelvic peritonitis, and from profuse menstruation. Both tubes were found at operation to be sclerotic. One-fourth of an ovary was left, and with this the patient had twice menstruated.

Kidney Removed for Pyonephrosis.—This specimen had been removed on March 4. The patient had come to him one year ago with a marked prolapse of the kidney. Operation had been suggested by him, but not urged. On her return last January the kidney was found to be very large and fixed, and the patient complained of a good deal of pain. At the operation the kidney was found to be made up of three abscesses, having been converted into a mere shell.

Intraligamentous Fibroid and Ovarian Cyst.—These specimens came from a woman, thirty-four years of age. The operation for the removal of the fibroid was done on March 21. The tumor was not attached to the uterus or to the broad ligament.

Tubo-Ovarian Cyst and Small Ovarian Cyst.—When this patient had first been seen a diagnosis of ectopic gestation was made because of the presence of a mass to one side of the uterus, which exactly resembled an ectopic gestation sac. On opening the abdomen this mass was found to be a tubo-ovarian cyst on the right side. There was also a small ovarian cyst on the other side.

Ovary in a Pocket of Broad Ligament.—On January 25, 1899, another surgeon had curetted the uterus of this patient, shortened the round ligaments and attached them to the anterior part of the fundus. The woman did not do well after the operation. The ovary, which was left, [illegible] enlarged and [illegible] were removed by Dr. [illegible] a few days ago. He could find no trace of a [illegible] on the left side. The tube which had been [illegible] at the first operation was found [illegible], and the ovary was completely [illegible] in a bed of the broad ligament.

The Treatment of Cancer by the X Ray.—Dr. Charles Warrenne Allen, before reading a paper on the above subject, presented a number of patients showing the results of the treatment. The subject was further elucidated by an exhibition of lantern slides. Dr. Allen said that he had observed in the practice of Dr. Pusey of Chicago such results from the use of the x-rays that [illegible] in the [illegible] he had recently added it to his armamentarium, using also the other well tried remedies. A long experience with the latter enabled him to determine how much of the result was due to the use of the x-rays. The paper was based upon the treatment of twenty-six cases. Of this number seven had been discharged, though they could not of course be reported as cured. One patient had disappeared too early to be told of anything being accomplished. One patient had died, though life had been prolonged and the patient made much more comfortable by the x-ray treatment. There were now thirteen cases under the treatment, and all were improving except one case of recurrent carcinoma of the breast, in which treatment had been interrupted because the patient had received a severe fall. One of the patients was a physician in active practice suffering from cancer of the rectum. He stated that he had been very greatly improved. The cases treated by him were undoubtedly cancer, and many of them had been pronounced by other physicians to be exceedingly severe if not absolutely hopeless.

X-Ray Dermatitis.—He had not had any severe x-ray burns, and this he attributed partly to the use of screens, and partly to the protection of the adjacent parts by the application of a solution of methylene blue in soda. The alkaline solution was used because it had been suggested that in cases of x-ray burn the alkaline reaction of the tissues was changed to an acid one. Dermatitis should be avoided if possible, but in some instances it was of decided benefit in hastening the cure. The treatment for such burns was the application of methylene blue in alkaline solution, or picric acid solution.

Apparatus.—He had used the static machine and the induction coil, and both had produced x-ray dermatitis in his hands. The large German bi-anodal tubes were very useful, but they were not only expensive but, if perforated, were a dead loss, because there was no place in this country where they could be exhausted. He had used both metallic and vulcanite screens, the latter having the advantage of not causing sparking.

The author drew the following conclusions: (1) The method was of decided value, though not without danger. (2) It was not a method likely to supersede or do away with previous modes of treatment. (3) The focus tube was of comparatively little importance in the treatment of cancer. (4) The method appeared to be of decided value in cases of recurrent cancer. (5) From present indications there seemed to be no reason why it should not be employed in primary cancer. (6) The exposures should be stopped at the first statement of the patient that a burning or prickling of the skin is felt. (7) In the early stages most cancers could be cured by the x-ray.

Dr. Albert C. Geyser said that Dr. Allen had evidently done some remarkably good work with the x-rays. He was himself treating with the x-rays a woman who had been operated upon for abdominal carcinoma by Dr. Pryor some time ago, and had required to be tapped every five or six weeks. She had been made very comfortable by the use of the x-rays, and the odor had been greatly reduced.

Dr. [illegible] said that there was reason to believe that the use of the x-rays would be greatly extended, and as they advanced those reporting cases should be most careful in giving the details of their method of treatment. The nature of the apparatus used, such as the length of the coil and the size of the wire, and the number of interruptions, should be stated. The [illegible] said that was very important and it was also well to state the nature of the interrupter used. If the static machine were used then the number and size of the plates should be recorded, as well as the number of revolutions made per minute. Whether the current was continuous or was interrupted by means of a spark gap, and whether the Leyden jars were used in series or not, should also be noted. Of course, the report should state what kind of vacuum tubes were used. There were two chief kinds of tubes, the plain tube and the adjustable tube. He had obtained the best results from the plain tubes. The distance of the tube from the patient was of much importance. A year and a half ago one member of the X Ray Association reported a number of cases of rodent ulcer as cured, whereupon another member suggested that the cases be reported upon again at the end of the year, because these patients, he said, had a habit of dying from the disease after having been reported as cured.

Dr. W. B. Snow spoke of an exceedingly severe case of rodent ulcer of the face that had shown very satisfactory improvement since he had been treating it with the x-ray.

Dr. Milton W. Franklin said that the vacuum tube had a given resistance, which for any one moment is absolutely invariable and can be measured in ohms. With a given voltage or electromotive force in a tube having a given resistance there would be a given quantity of current transmitted. These measurements, in the case of x-ray tubes, had never been made. The exact electromotive force of static machines giving sparks above one inch had never been determined. With the static machine the difference of potential between the two poles steadily increases until the poles become "saturated"; then if the poles are near enough to allow the accumulated charge to pass through the intervening air, a spark will result, and a discharge will take place. As the machine continued to run there would be a fresh accumulation and another spark discharge. This supposed that no tube was in use. When a tube of given resistance was interposed and a sufficient charge had accumulated to overcome this resistance a spark would pass. At no time would the difference of potential in the machine be greater than that necessary to overcome this resistance—in other words, with a low tube there would be a greater number of discharges than if a high tube were used. In each case the amount of electricity would be equal to the electromotive force divided by the resistance of the tube. With the coil it was different. No matter what the resistance of the tube there would be as many discharges as there were interruptions in the primary current. The voltage in the secondary coil was the same in every case. The voltage was absolutely constant, and with a low tube there would be a larger amount of current passing.

Dr. Allen closed the discussion. He said he had used both high and low tubes, or hard and soft tubes, and was now using the hard tubes in preference. All of the burns that he had seen had occurred with the static machine and with very low tubes. Some patients were more susceptible than others, but this individual variation was within rather narrow limits. In a severe case of cancer he had formerly made use of exposures of half an hour; now he was using much shorter exposures, and repeating the treatment more frequently. Some of the cases formerly receiving twenty minutes' treatment were now receiving exposures of eight minutes. For the treatment of cutaneous affections he was in favor of bringing the tube very close to the diseased area—say, two inches. For the more deeply-seated cancers the distance was probably eight or ten inches.

Officers Elected.—*President*, Dr. Alexander Lambert; *First Vice-President*, Dr. Wilbur B. Marple; *Second Vice-President*, Dr. Frederick P. Hammond; *Secretary*, Dr. Ogden C. Ludlow; *Corresponding Secretary*, Dr. Frederic W. Loughran; *Treasurer*, Dr. Charles E. Denison; *Member of Executive Committee*, Dr. Parker Syms; *Member of Nominating Committee*, Dr. E. Eliot Harris.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 26, 1902:

	Cases.	Deaths.
Measles	480	22
Diphtheria and croup	295	51
Scarlet fever	434	17
Smallpox	56	13
Varicella	69	..
Tuberculosis	248	154
Typhoid fever	26	6
Cerebro-spinal meningitis	..	5

Test for Blood Stains.—In 1898 and 1899 M. Bordet showed that by injecting the defibrinated blood of any animal into the blood of animals of different species the serum of the latter acquired, after a time, the property of agglutinating and of dissolving the corpuscles of the blood of the former. Moreover, he showed that the serum mixed with the defibrinated blood of any other species formed, after a few minutes, a clear, limpid, red liquid, while if it were mixed with the blood of the animal from which the blood had first been injected, it formed an opaque liquid from which a flocculent mass was quickly precipitated. His experiments, which gave a test for blood stains, have been repeated and extended. Mr. Uhlenhuth has applied it to blood from oxen and rabbits. Every week he injected 10 cubic centimeters of defibrinated ox blood into rabbits, and after five such injections he obtained a serum that dissolved all blood except that from oxen. Analogous experiments with human blood gave like results. It was possible to discriminate between drops of human and of ox blood that had been left to dry for a month on a wooden plank.

Messrs. Wassermann and Schutze have carried such processes further and have experimented on the blood of twenty-three species of animals, and confirmed the former conclusions. The serums were a perfect test. It is noteworthy that the blood of monkeys and of men were somewhat similar in action. Spots of blood three months old could be discriminated. The importance of this discovery to medical jurisprudence is very great.—*New York Sun.*

An Evil Consequence of Pince-nez.—Mr. Robert D. Joyce, Ophthalmic Surgeon to the Richmond Hospital, Dublin, calls attention to a very curious point in regard to the use of pince-nez, namely, that in some cases it sets up a flow of tears in consequence of its pressure dragging on the tissues at each side of the nose to such an extent as to pull the lower lid out of position, and prevent it lying properly in contact with the bulbar conjunctiva. In the cases observed the displacement of the lid, with, of course, the inferior punctum, was small in amount, only about 0.2 or 0.3 m.m. This might easily escape detection, and all the more so, as it has to be looked for while the glasses are on the patient's face. But even this small amount of eversion is amply sufficient to cause epiphora. This, he says, is a very important matter, for such an eversion of the lid, though present at first only when the pince-nez is actually on the face, will become permanent in time, and set going all the troubles associated with ectropion. In a large proportion of cases pince-nez will set well on the face, but in a certain number they are unsuitable for the above reason, even though they may be a "good fit," so far as the optician is concerned. In some cases it is not possible to fit pince-nez without causing this kind of ectropion, and in such, of course, spectacles must be used.—*The Hospital.*

Probing by Telephone.—In several London hospitals surgeons are now using the telephone whenever they have occasion to probe for bullets or other metallic objects. The receiver of the telephone is placed on the head of the operator, and the patient is placed, in the usual manner, in contact with a plate; the general medium employed being a wet sponge or some paper saturated with a saline solution, which is spread over the plate. The latter is connected with the telephone by a wire, and the probe, after it has been introduced into the body, naturally vibrates as soon as the foreign metallic substance comes in contact with it.

The probe is also connected with the telephone by a wire, and thus no such blunder is possible as sometimes happens when an ordinary battery is used.

When a telephone is used in this way the plate acts as one pole and the probe as the other. Needles, bullets, grains of shot and pieces of steel and copper can be easily located by the use of this simple method. Indeed, it is said that the only instances when the telephone did not work satisfactorily were when the objects to be located were of the same metal as the probe.

Eminent French and German surgeons have been watching these experiments in London, and intend to introduce the same method into the hospitals of Berlin and Paris.—*New York Herald.*

The Scale of Professional Envy.—An Italian philosopher, Signor Ferriani, has amused himself by constructing a scale of degrees for the measurement of professional envy. The highest point in this envy measurer is 10. Architects are happily placed lowest on the scale. They register only 1; advocates and priests and military men are ranged at 2, and in the ascending scale he gives us professors of science and literature, 4; journalists, 5; authors, 8; physicians, 9; actors and actresses, 10. The small amount of envy among architects is held to be due to their precise, severe, and rigid studies. The same thing applies to advocates. Among the clergy envy is found mostly in preachers. In the military career envy is quiescent in time of peace, but can become acute in time of war. Envy makes men of science and literature lead solitary lives, diffident of each other. Among physicians envy is still more prevalent, and they do not spare their colleagues, often terming them charlatans. In the theatrical world envy, according to Signor Ferriani, reaches its acute form, vanity playing a great part in its production.

Expectation of Life.—In part 2 of Biometrika, a journal which has recently been established for statistical study of biological problems, there is an interesting article "On the change in expectation of life in man during a period of circa 2,000 years," by Professor Karl Pearson. As the outcome of a comparison between the recorded ages of death of a certain number of Egyptian mummies and the rate of mortality of our own times. Professor Pearson calculates that to-day a man of twenty-five years lives on an average fifteen years more than a man of twenty-five years did 2,000 years ago, thus suggesting that, in the course of these centuries, man is remarkably fitter to his environment, or else he must have fitted his environment, immeasurably better to himself. Whichever be the correct explanation, both conclusions point perfectly definitely to an evolutionary progress. We wonder what will be the expectations of life 2,000 years hence.—*Edinburgh Medical Journal.*

Hebrew Charities' Work for March.—In the month of March, 2,044 families and individuals applied at the Relief

[illegible]

Advantages of Several Meals a Day.—Professor W. O. Atwater [illegible]. The theory is advanced from time to time that one or two meals a day are preferable to the three commonly served in this country. If the same amount of food is to be eaten it is hard to see the advantage of two very hearty meals over three ordinary ones. The best physiological evidence [illegible] that [illegible] quantities of food taken at moderate intervals are more easily and completely digested by ordinary people than larger quantities taken at long intervals. If the food ordinarily taken is considered excessive and the aim is simply to reduce the amount, it would seem more rational to make all the meals lighter than to leave out one. The very fact that the custom of eating a number of meals has so long been almost universal indicates that it must have some advantages which instinct, based upon experience, approves and justifies.

Milk Adulteration in Athens.—A French newspaper describes an ingenious method of milk adulteration practised in Athens. The residents have a penchant for goat's milk, and herds of these animals are led along the street by milk sellers wearing long blouses with capacious sleeves. Their cry of 'Gala! gala!' brings the housewife to the door, and she prudently demands that the goat shall be milked in her presence. This is done, but the milkman has in one hand the end of a thin tube which runs up his sleeve and connects with an india rubber receptacle full of water, which is carried under his ample blouse. At each pressure of the fingers on the udder there is a corresponding compression of the water sack, and milk and water flow side by side into the milk pail.—*Boston Evening Transcript.*

Æstival Quotidian Fever (True Quotidian).—Attilio Ca[illegible]ni reports his researches in sixty-two cases of quotidian fever. He examined the blood every three hours, and states that the life cycle of the parasite always followed the characteristic course pointed out by Marchiafava and Bignami, and always exhibited the differential signs distinguishing it from malignant tertian. Further experimentation, consisting in the inoculation of healthy persons, with resulting fever of a quotidian type, proved the existence of a variety of æstival parasites which determine a fever of quotidian type and complete their life cycle within twenty-four hours. Experiments in the reproduction of the quotidian type of fever, through the sexual cycle in the body of anopheles, are at present under way, and will be reported later.—*Il Policlinico.*

Cancer Investigation in Great Britain.—The Royal College of Physicians and the Royal College of Surgeons together have sanctioned a scheme for the systematic investigation of cancer. It is proposed to raise $500,000 for a special laboratory to work under the direction of the most distinguished medical scientists. It is feared that the scheme is too laboratorial, inasmuch as the vital discovery, namely, how to prevent or stay the course of cancer, is more probable to be made [illegible] and [illegible] study of the living organism [illegible] in a laboratory. That study [illegible] of the [illegible] and [illegible].—*New York [illegible].*

Physicians' Fees.—The highest fee ever offered [illegible].

Cholera Plague.—The great epidemic of [illegible] in [illegible].

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended April 26, 1902:

REMARKS ON ARTERIOSCLEROSIS.*

By I. ADLER, M.D.,
NEW YORK.

I wish to bring to your attention this evening the subject of arteriosclerosis. I do not propose to enter at length into the complicated and still very obscure questions of pathology and the many mooted points of clinical history. I wish to present merely a few thoughts and reflections that may, perhaps, be of general interest, and, possibly, of some practical use.

A vast amount of histological and experimental work has been devoted to this subject in the last twenty years; and much clinical and statistical material has been carefully collected, but we are still very far removed from any really satisfactory understanding of the questions involved. The very term itself—arteriosclerosis—has by no means a stable and universally accepted significance.

Since the brilliant researches of Thoma and his school, arteriosclerosis has been very generally looked upon as primarily a disease of the media or muscular coat of the blood vessels. If the muscular layers lose their elasticity and contractility, be it from over-strain, be it from senile exhaustion, or from disease, the vessel must become distended by the blood pressure; the current is retarded, and as the result of an attempt at self-adjustment, connective tissue is formed in order to restore the proper caliber of the blood vessel. By most ingenious methods, Thoma has established this beyond doubt, and has shown, too, how the well-known tortuousness of the blood vessels, the secondary degenerations, ulcerations, calcifications and ossifications must necessarily follow. This most plausible and enticing theory is now generally accepted in preference to those of Huchard, Traube, and others. A somewhat closer scrutiny, however, leads to the conviction that while very many of the more prominent phenomena are undoubtedly accounted for by this theory, it does not suffice for a complete and exhaustive explanation of all the facts. We are compelled to acknowledge that no theory that takes account of a single factor only can suffice to cover all the phenomena in so complicated an organism as the human body, and that methods of explanation based on mere mechanic concepts are inadequate. Thoma's theory provides a sufficient explanation for the lesions, gross and histological, in the larger and largest vessels, the aorta, iliacs, carotids, radial, etc., but it does not, or so, at least, it appears to me, sufficiently account for the alterations in the smallest vessels and in the parenchyma.

It can, I believe, be taken as a fact, proved by the study of numerous cases in all stages of development, that in every instance of arteriosclerosis, the process is not confined to the blood vessels alone, but that the organs and tissues participate in the form of interstitial inflammation or proliferation, ultimately leading to circumscribed or diffuse fibrosis. It is an open question whether the proliferation of the interstitial tissue is the primary process and the sclerotic affection of the blood vessels secondary to it, or *vice versa*. But of this there is no doubt, that every arteriosclerotic vessel is associated with more or less complete fibrous induration of the territory it supplies. Arteriosclerosis and interstitial induration, ultimately leading to fibrosis, invariably go together. Experimental and histological experiences, which, however, are not as yet sufficiently advanced to warrant positive conclusions, have made it appear possible, and even probable, to me, that arteriosclerosis in many instances begins primarily in the smaller and smallest vessels of the various organs and thence extends upward into the larger trunks. If this is so, we must transfer the point of origin of arteriosclerosis to the small vessels and the interstitial tissue. The arteriosclerosis of arterioles and the fibrous induration of the parenchyma, as the primary lesion, produce the local increase in blood pressure and the retarding of the blood current, which, together with the progressive alterations in the blood vessels from below upward, form a firm foundation, on the basis of which Thoma's theory, with its mechanical and physiological deductions, can then be utilized to account satisfactorily for all the observed facts.

But what causes the primary sclerosis of arterioles and interstitium? It is evident that considerations taking account of purely mechanical factors will not help us here, and we are naturally, and almost by necessity, led into the domain of chemical and metabolic changes. It is certainly not intrinsically impossible that definite local or systemic metabolic derangements can be conceived as a cause for indurative and degenerative lesions in blood vessels and connective tissue. The club fingers in suppurative pulmonary lesions and in certain intoxications may be cited as an apposite illustration. More striking still is the condition of the connective tissue group in myxœdema and in acromegaly. I am well aware that all this is as yet largely hypothetical, and in no wise strictly proven, but this hypothesis seems to explain a great number if not all of the observed facts, and thus far at least there are, to my knowledge, no well-founded observations to contradict it. And, after all, this view is not so purely speculative as might at first appear. Aside from the analogies just mentioned, there are a number of well-grounded facts which distinctly speak in support of it. We know that there are many and important chemical changes in the metabolism of the senile, and senile arteriosclerosis and fibrosis is the most frequent and typical of all forms. We find local and general arteriosclerosis associated with various intoxications (alcohol, nicotine, lead, etc.). We find it almost regularly in gout. It must be noted, however, that there are certain, but, perhaps, not very essential histological differences between the earlier stages of these toxic forms of arteriosclerosis and the typical senile form, but ultimately, and this is certain, they one and all lead to the same type of general arteriosclerosis, atheroma, and degeneration.

Summing up this part of the subject, we note, ment that arteriosclerosis may be conceived as commencing in the smaller and smallest vessels, and that it is always and without exception associated with indurative processes in the tissues and organs. It may begin as a purely local process in a single viscus—the heart, the kidneys, the brain, etc.—and gradually become generalized. Second, it is by no means always a disease of advanced age or senility, but it may make its appearance at any period of life, even in infancy and childhood. Thoma himself states that milder grades of arteriosclerosis are very frequent after the age of thirty-five. Young observed typical sclerosis of the temporal arteries in a child of fifteen months. Meigs found sclerosis of the coronary artery in an infant five months old. Among 148 autopsies of arteriosclerotic subjects Seitz found seventeen, whose ages ranged from ten to twenty-nine years. Many more examples might be cited. All these data, moreover, refer to the grosser changes found in the larger blood vessels. It is my conviction that the disease will be recognized still more frequently in comparatively young subjects when the condition of the smaller vessels and of the interstitial tissue is made an object of more careful investigation. Third, it is possible that chemical changes may be important factors in its etiology, and we recognize at present besides the senile forms of the disease arteriosclerotic conditions produced by various toxic influences. It is probable, too, that hereditary disposition is a not infrequent and important etiological factor.

---

*Read before the New York County Medical Association.

If we now proceed to consider, from the point of view thus gained, the clinical aspect of our subject, we shall find it a very complex and difficult one. There is no great difficulty in recognizing the tortuous vessels, the senile arch, the hard and rigid radial artery, and all the manifold organic lesions associated with general arteriosclerosis of the aged; but the appreciation of localized arteriosclerotic lesions and more especially in the case of young individuals, is by no means always an easy task, and this is the more true, inasmuch as there appears to exist no one single symptom that can be relied upon as absolutely pathognomonic. The well-known accentuation of the second aortic sound and Litten's symptom are undoubtedly characteristic and pathognomonic symptoms when present, but their absence proves nothing. Grave arteriosclerotic processes may be going on in various parts of the body—brain, kidneys, liver, etc.—without, for a long time, at least, causing recognizable symptoms in the aorta and the large vessels. Maragliano has shown that the increase of blood pressure, as far as can be clinically demonstrated, and which has so long been considered characteristic of arteriosclerosis, is by no means a constant symptom. In five cases of arteriosclerosis, in which he studied the blood pressure by accurate methods, he found only one in which the pressure was abnormally high. Hypertrophy and dilatation of the left ventricle of the heart is present only in a limited number of cases, the pulse may be very slow or quite rapid or entirely normal. Therefore, as no single pathognomonic symptom exists, each case must be carefully studied on its own merits and with reference to its own peculiar features.

According as different vascular territories are primarily or more prominently affected, several clinical types of arteriosclerotic disease may be distinguished, but it must always be borne in mind that these types are not absolutely fixed and permanent, but may merge one into the other, for the process is largely progressive; one organ after the other becomes diseased, and if life is not previously ended a very general arteriosclerosis of the entire system ultimately develops.

One well-known type may be called cardiac. Here we have arteriosclerosis of the coronaries and the aorta. Numerous histological studies have convinced me that in the heart the arteriosclerotic lesions commence in the finer and finest branches of the coronary arteries and are associated at the very outset with indurative lesions of the myocardium. By the time that gross lesions appear in the trunks of the coronaries and in the aorta numerous smaller branches in the heart muscle and their surrounding territory have undergone degeneration and the process leads to a condition of diffuse myofibrosis recently well described by Dehio. The clinical symptoms of this group are well known and need no detailed description here. But it is well to bear in mind that in the early stages physical examination proves practically negative. There are no murmurs, no hypertrophy or dilatation. The symptoms, if any, are mainly subjective and not at all characteristic. There may possibly be a slight abnormality of the pulse, either bradycardia or rapid and somewhat feeble pulse, particularly on slight exertion, or distinct arhythmia and intermittence. In the somewhat later stages accentuated second aortic sound, hypertrophy and dilatation of the left ventricle, later still of the right also, may be found, secondary murmurs develop, angina pectoris and kindred affections make their appearance, and as the degeneration of the heart muscle proceeds, all the well-known symptoms of heart insufficiency follow.

Another type may be called renal. Here, too, there is every reason to believe that the process commences in the arterioles and the interstitial tissue, and progressively and gradually involves larger portions of the kidney. The early stages of this group of cases can, probably, never be recognized clinically. There are, as a rule, no subjective complaints. There is no abnormal renal secretion, and the urine, if by any chance it is examined, will, probably, show no albumin. A somewhat later stage is usually recognized by mere accident. There are still no very positive subjective symptoms, an occasional headache is not referred to any renal lesion; not infrequently an accidental examination, as for an insurance company, for instance, calls the attention of the patient to the fact that there is some lesion. At this stage the urine presents the well-known characteristics, a rather low specific gravity, though not always excessively low, only occasionally a trace of albumin, but the constant occurrence of granular casts in the sediment. In its further progress all the characteristic symptoms and sequelæ of chronic contracting kidney are more or less rapidly developed, together with progressive arteriosclerotic lesions involving the heart, blood vessels and other organs.

The following case may be of interest as illustrating some of the points here mentioned, and as again showing how insidious is the beginning of this disease, and how very grave symptoms may suddenly develop with scarcely any appreciable physical signs:

Mr. W. G., about forty-two or forty-three years old, of apparently good constitution and robust build, had always been perfectly healthy, with the exception of the ordinary minor ailments. He was rather a high liver, and at one time had smoked excessively. He never had gout; used alcohol only in moderation. Father and brother had died at a comparatively youthful age of heart disease, the exact diagnosis not obtainable. In consequence, Mr. G. had all his life dreaded heart disease for himself, and was of late years frequently examined with entirely negative results. Latterly, he had reformed his habits and became very careful as regards diet and the use of tobacco. He was passed by several insurance companies without difficulty. The last attempt at insurance failed because the examiner detected a trace of albumin. Repeated examinations showed an occasional minute trace of albumin in a urine of average specific gravity of about 1020, but no casts could be found, not even with the aid of the centrifuge. During all this time the man appeared to be in perfect health. While traveling abroad he was taken one night, suddenly and without premonition, with what he called an attack of asthma, but which the physician who was summoned recognized as an unmistakable attack of pulmonary œdema. There was a great deal of præcordial distress, a very rapid and feeble pulse, almost continuous short cough, considerable dyspnœa, some cyanosis, and large and small râles all over the chest. In the morning all these symptoms had disappeared, leaving the patient somewhat weak and badly frightened. I saw the patient a few weeks afterward. Since this first attack he had had a second but slighter one. Careful examination of the whole body gave but very scant results. The heart was neither dilated nor hypertrophied. There were no murmurs. Lungs, liver, spleen, etc., appeared perfectly normal. No arteriosclerotic arteries could be seen or felt. The second aortic sound, however, was distinctively accentuated, and there was a faint suggestion of galloping rhythm, which became more marked on even slight exertion. The pulse was somewhat feeble and rapid. The urine, specific gravity 1018, contained occasionally a slight trace of albumin, and here and there, but by no means regularly, were granular casts found. Notwithstanding these very slight physical signs, the diagnosis of primary arteriosclerotic kidney, with subsequent arteriosclerosis of the heart and aorta, was made and the prognosis was set down as an absolutely bad one. It is particularly interesting to note in this case that pulmonary œdema was practically the very first symptom that became manifest. From this time on the disease progressed rather rapidly, the left heart hypertrophied, both ventricles became dilated, all sorts of murmurs made their appearance, liver and spleen began to enlarge, attacks of pulmonary œdema became more frequent and severe, ascites and anasarca set in, and the man died four years after the first attack.

Another group of arteriosclerotic symptoms may be distinguished as the cerebral type. As to the first histological development, I am unable to speak from experience, and I believe that a careful microscopic investigation is urgently needed. The larger vessels and their anatomical lesions have, however, been well studied. The clinical symptoms are well known and require hardly more than mere mention. We are all familiar with the diffuse unlocalized headaches, the vertigo, particularly on change of position of the head or of the eyes. This type leads frequently to apoplectic hemorrhages and to softenings. That we have to deal here also with indurative processes in the interstitium is plainly evidenced by the psychic symptoms, which so frequently are associated with these forms of arteriosclerosis: the disturbance of memory, the psychic apathy or irritability, the various forms of so-called senile dementia have their anatomical basis, undoubtedly, in the more or less progressive arteriosclerotic induration of the cerebral tissue, especially the cortex.

These three types of arteriosclerosis, the cerebral, the renal and the cardiac are well known, and have frequently been discussed. I am tempted to suggest two others, which as yet have not, so far as I know, been recognized. One is a spinal type of arteriosclerosis, which may be considered as possessing distinctive features. In these cases, usually in more or less senile subjects, with more or less strongly marked general arteriosclerotic signs, the symptoms to a certain degree simulate tabes, and are not infrequently diagnosed as such. They differ, however, from locomotor ataxia in many and important points, above all in the lack of progressiveness, and of all typical sequence of symptoms. I do not, however, wish to go beyond this mere suggestion, particularly as no anatomical material is as yet at hand.

The second type, which I also merely wish to suggest, in order to invite clinical and histological research of other workers in this field, may be designated as the gastrointestinal type, including under this heading also the liver and pancreas. My own studies, both clinical and anatomical, though by no means as yet resulting in positive conclusions, have made it very probable to my mind that there is a set of gastric, intestinal, and cirrhotic symptoms in arteriosclerotic subjects, all of them depending on indurative and atrophic conditions of stomach, intestine, pancreas and liver, which are the direct consequence of arteriosclerotic indurations. As clinically illustrative of this may be mentioned the peculiar gastric condition so often met with in senile subjects, characterized by a diminished production of HCl, and insufficient and retarded muscular action. Anatomically, we find pressure atrophy of the glandular elements and extensive indurations of mucous, submucous and muscular coats. A similar condition is found in various portions of the intestinal tract, especially in the colon, and also in certain portions of the small intestine, accounting for many intestinal disturbances, such as constipation and atonic distension. The pancreas has been found in many cases of arteriosclerosis in a considerable state of fibrosis. We have thus far no material for determining if in these cases the ferment secretion of the pancreas has suffered. Perhaps the glycosuria, mild but constant, so very frequently found in aged arteriosclerosics, may, at least in part, be due to this arteriosclerotic fibrosis of the pancreas.

I am afraid, however, that I have already ventured too far into the domain of speculation, and will, therefore, stop to say, in conclusion, a few brief words on the subject of therapeutics, though this is even more unsatisfactory than the theory. It is evident that at a time when it becomes possible to diagnose arteriosclerotic lesions the process must have already advanced to some considerable extent, and it is quite hopeless in our present state of knowledge to attempt to restore indurated vessels and tissues to their normal condition. The utmost we can hope for is arrest of the progress of the lesion. This route is clearly indicated where the toxic influences are known, and where syphilis, alcohol, lead, nicotine, etc., are the underlying cause of the arteriosclerotic processes. These must be primarily dealt with, each according to the proper method. According as the heart, the kidneys, the brain, the stomach, etc., are more in the foreground of the picture, they must be treated according to the symptoms. In every case of arteriosclerosis, however, I would again urge, besides the special drugs that may be employed, the systematic use of the iodides. But, after all, according to our present lights, our treatment of arteriosclerosis must be mainly prophylactic. Both as a prophylactic measure and as a possible means of arresting the progress of the disease, diet undoubtedly plays a great rôle. In this connection Rumpf, on the basis of very careful investigations concerning the economy of the lime salts in the human system, has suggested diet schemes for arteriosclerotics and individuals with arteriosclerotic tendencies. Our knowledge of physiological chemistry, as a whole, and of the chemistry of arteriosclerosis in particular is, however, still so utterly inadequate as to preclude, for the present, any absolutely specific dietary or chemical measures. We are forced to fall back upon the general dietetic and hygienic laws as borne out by common sense and the experience of a thousand generations. Above all, no hard and fast rules, but possible adaptability of method to the needs of each individual case.

THE INDICATIONS FOR NEPHRECTOMY, WITH REPORT OF THREE CASES.*

By JOSEPH WIENER, Jr., A.B., M.D.
NEW YORK
ASSISTANT ATTENDING SURGEON, MOUNT SINAI HOSPITAL

The indications for the surgical removal of the kidney are to-day most manifold. For convenience, I shall divide them into three classes, according to the age of the patient: (1) During infancy, (2) During adolescence, (3) During adult life.

I shall not attempt to discuss all the rare forms of kidney disease that may necessitate nephrectomy, but shall limit myself to the more common ones. Of the three cases to be included in this paper, all of which were admitted to Dr. Lilienthal's service at Mount Sinai Hospital within the past year, and operated on by me, one belongs to each of the above-named classes. It is a source of gratification that, though each one had some unusual or serious complication, yet all three made complete recoveries.

The diagnosis of the surgical diseases of the kidney is made (to quote from the article on "Kidney" which I had the privilege of contributing to the Mount Sinai Hospital Reports for 1899) from (1) History of the case. (2) Examination of the abdomen with and without anæsthesia. (3) Examination of the urine (*a*) voided from the bladder; (*b*) drawn from the bladder (catheter); (*c*) drawn by the ureteral catheter. (4) Examination of the bladder and ureters (*a*) by cystoscope, (*b*) by ureteral catheter. (5) Examination with Rontgen rays. (6) Exploratory operations on bladder, kidney, or ureter.

The *other* kidney plays a very important rôle in every case of contemplated nephrectomy. Unless we have some reliable information as to the functionating capacity of the opposite kidney, we have no right to perform a nephrectomy. Clinical experience has demonstrated, however, that it is not essential to have a perfectly sound kidney on the opposite side before removing a diseased kidney.

Of the functionating capacity of the remaining kidney we must nevertheless have some knowledge. How can we obtain this knowledge before undertaking a nephrectomy? The chief means at our disposal are:

(1) The use of the cystoscope and ureteral catheter. (2) The palpation of the opposite kidney. (3) Opening the peritoneum before removing the kidney, and thus exploring the opposite kidney (*a*) by enlarging the incision for nephrectomy; (*b*) by making a preliminary separate incision. (4) By doing a preliminary nephrotomy on the diseased side and draining the kidney before removing it. The urine that escapes from this kidney is examined, and likewise that coming from the bladder.

The cystoscope is a great aid in diagnosis. But, although we can with it diagnose a diseased kidney by seeing purulent or bloody urine emanating from a ureter, we cannot conclude that the other kidney is healthy because the urine from that side appears clear. The urine may appear clear, and yet the kidney may be the seat of amyloid degeneration, of a new growth, of calculi, or there may be diseased foci in the parenchyma, which do not communicate with the pelvis of the kidney, and hence do not modify the character of the urine. Regarding the value of ureteral catheterization, we may exclude its use from those ureters from which we have seen bloody or purulent urine escape, for, in these cases the cystoscope has already made the diagnosis for us. We may confine the catheterization to those ureters from which the urine flows clear, as seen with the cystoscope. As the ureteral catheter can only remain in place a limited time, the amount of urine collected from one kidney must be small. The examination of such a small quantity of urine must necessarily often be unsatisfactory, and frequently will turn merely on the question of the presence or absence of albumin. Moreover, even the absence of albumin from such a specimen of urine is far from positive proof of the soundness of the kidney from which it flowed. The presence of red blood cells would be no proof of kidney disease, since a slight abrasion of the mucous membrane of the ureter might very well be the source of the blood. But there is another side to the question of ureter catheterization. Are there any dangers connected with it? The diseases of the kidney that are most apt to be bilateral (and in consequence the catheterization of the ureters of great value) are the purulent and the tubercular. Is there any danger of infecting a healthy ureter by inserting a catheter into it through an infected bladder? There is some difference of opinion as to whether renal tuberculosis is ever ascending. That a purulent kidney is frequently the result of a cystitis is unquestioned, we have but to refer to cases of bladder infection by catheters, followed shortly by bilateral pyelonephritis. In like manner, gonorrhœal kidney diseases are certainly examples of ascending infections. As a matter of course, the bladder should be thoroughly irrigated before introducing the cystoscope, but we know we cannot thereby render an infected bladder sterile. Moreover, if the infectious material comes from the other kidney, it will be continuously flooding the bladder while we are introducing the ureteral catheter. Since purulent and tubercular renal diseases are either the result of pre-existing bladder disease or secondarily infect the bladder, it is obvious that, to reach the ureter, we must pass the catheter through a bladder that is the nidus for micro-organisms. There certainly must be some danger of infecting a healthy ureter and through it a healthy kidney. Henry Morris sounds a note of warning when he remarks: "The cystoscope and the ureteral catheter should be employed with reserve and with great caution in tuberculous disease."

To discuss in detail the relative value of the various other methods for ascertaining the condition of the opposite kidney would lead too far. Suffice it to say that the employment of one or more of the methods above enumerated, combined with a careful study of the history of the case and repeated urinary analyses, will, in a large majority of cases, enable us to decide whether, in the first place, there is a kidney present on the opposite side; and whether, in the second place, it can properly perform its work.

I.—*The indications for nephrectomy during infancy* fall into two groups: (1) Congenital malformations, and (2) New growths. The congenital malformation usually consists of an obstruction to the flow of urine from the kidney into the bladder. The seat of the obstruction may be at the bladder end of the ureter, or at the kidney end, or at any part of the ureter between these two points. Sometimes the lower part of the ureter is entirely impervious. As a result of the obstruction to the flow of urine, a hydronephrosis develops. This hydronephrosis may attain an enormous size, and the kidney parenchyma may become completely obliterated, the kidney being transformed into an enormous cystic sac. I have not been able to find any cases of congenital hydronephrosis that survived a nephrectomy in the first nine months of life, although I have been informed that there are a few on record.

---

*Read before the Harlem Medical Association on January 2, 1902.

Case I.—Samuel A., nine months old, admitted to Dr. Lilienthal's service at Mount Sinai Hospital, August 21, 1901. The parents of the child were alive and well. The child had always been constipated. With the exception of this, the parents had noticed nothing abnormal about the child until six weeks before its admission to the hospital. At that time a hard tumor was noticed on the left side of the abdomen. The abdomen gradually increased in size; the child had attacks of restlessness, fever and vomiting. It took but little food, and lost considerably in weight. The stools had often been greenish, and the mother reported that the child had urinated more frequently than formerly. Examination showed a well-nourished child; the tongue was moist and coated. The lungs, heart and liver were normal. In the abdomen there was a very large mass, occupying almost the entire left side, and extending over to the right iliac fossa; its surface was rounded and smooth, and the whole tumor was somewhat movable. The lower portion of the tumor was of softer consistency than the upper. There was no tympany over the tumor.. Splenic dulness merged into the dulness of the tumor. The tumor could be moved towards the left lumbar region, and well over to the right side. By rectum, the tumor could be felt above the pelvic brim. Temperature, 100°; pulse, 110; respiration, 26. Operation on August 24, 1901, under chloroform. I made an incision about 12 cm. long, extending from the left side of the umbilicus backward and slightly upward into the lumbar region. The muscles were, in part divided; in part, separated bluntly. Upon opening the peritoneum, a large tense tumor at once presented itself; its surface was smooth and covered with peritoneum. On account of the great size of the tumor, the exact location of the pedicle could not be determined. The tumor was aspirated and found to contain a clear, colorless fluid; about 750 grams of fluid were withdrawn. The collapsed sac was then drawn into the wound. Its pedicle was intimately adherent to the omentum and to a loop of small intestine; but, as the child's condition was alarming, no attempt at further exploration was made. The adherent omentum and, at the same time, the vessels in the pedicle were tied off with catgut, applied as a chain ligature, and the cyst cut away. A few small bleeding vessels in the omentum and on the adherent loop of intestine were ligated. On account of the straining of the child, the prolapsed loops of gut were replaced with some difficulty, due to the fact that the anæsthetic had to be stopped soon after the beginning of the operation. The opposite kidney was palpated through the wound and felt normal. The wound was rapidly closed with through and through silk-worm-gut sutures, a small drain being left at the posterior angle. Time of operation twenty-seven minutes.

Examination of the tumor showed a smooth thin sac, in which numerous small subdivisions (calyces?) could be demonstrated. A small portion of the ureter (patent) remained attached to the tumor. The pathologist could find no trace of kidney tissue. There was considerable shock following the operation, and active stimulation was necessary. August 25, pulse, 180; temperature, 103.4°. Drank considerable water, and urinated freely. Steady improvement until August 28, when a bronchopneumonia was detected by Dr. Heiman on the left side posteriorly. The inflammation of the lung cleared up in a few days, the wound healed by primary union, and the child left the hospital well, nineteen days after operation.

Tumors of the kidney in children occur with maximum frequency during the first five years of life. The disease is generally a sarcoma, which originates in the connective tissue in the hilum, and spreads into the renal parenchyma. Rarely is there an obstruction of the ureter, or an ulceration into the calyces; hence we seldom find hydronephrosis or hæmaturia. The first symptom in most cases is tumor. Heresco, quoted by Morris, states this to be so in 81 per cent. of the cases; while pain was the first symptom in 14 per cent., and hæmaturia in only 5 per cent. This contrasts strikingly with malignant disease of the kidney in adults. The earliest successful nephrectomy for sarcoma that I have been able to find in literature was reported by Schmidt, who operated on a child of six months, and there was no recurrence after four years.

II.—*The indications for nephrectomy during adolescence* consist, in the majority of cases, in the presence of a pyelonephritis, or of a septic nephritis of hæmatogenous origin, following in the wake of one of the acute infectious diseases. A kidney already the seat of disease is more prone to be affected, but even a perfectly healthy kidney may become so badly infected as to necessitate its removal. The following is a case in point:

Case II.—Hyman G., thirteen years old, admitted to Dr. Lilienthal's service at Mount Sinai Hospital, March 11, 1901. The family history was negative as to tuberculosis. Seven years before admission the boy had had some kind of fever lasting about a week. Otherwise he had always been well, with the exception of several attacks of tonsillitis, the last one about six weeks before his admission to the hospital. The parents stated that previous to his admission the boy had been sick only twelve days, complaining of frequent and painful micturition and of pain in the left lumbar region. During this time he had had several chills and more or less fever, night sweats and diarrhœa. Examination showed a poorly-nourished and undeveloped boy. The tongue was moist and very red; the throat was normal. At the apex of the heart there was a systolic murmur transmitted to the left. The lungs were normal. The abdomen was somewhat distended. In the left lumbar region, posteriorly, there was a distinct point of tenderness. On bimanual examination an indistinctly fluctuating mass could be made out in this region. The right kidney could not be palpated. Rectal examination was negative. Examination of the urine showed it to be clear, acid, 1020; urea, 1.5 per cent., containing a trace of albumin, no sugar, and only a few pus cells by microscope. Temperature, 103.8°; pulse, 110; respiration, 28. Operation on March 12, 1901, under gas and ether, with a view to incising a perinephritic abscess. An incision was made in the left lumbar region, parallel to the free border of the ribs. A small abscess was opened posterior to the kidney, and a large one anterior to it. The kidney was small and, apparently, normal. The abscesses were drained with tubes and gauze, and the wound left open.

Following the operation the boy did not improve. The temperature rose almost daily to 103° F. From

March 12 to March 23 the average amount of urine excreted in twenty-four hours was 11 ounces. The urine was clear, contained no albumin, 1.5 per cent. urea, and by microscope only a few pus cells. Second operation on March 23, under chloroform. The wound was enlarged and an abscess opened above the kidney under the diaphragm. To secure better drainage, the last rib was resected in the axillary line. In so doing the pleura was opened, and a small iodoform-gauze packing was at once introduced into the pleural cavity. In enlarging the wound around the kidney the posterior layer of the peritoneum was opened, and a packing introduced. The whole wound was left wide open. The right kidney was found, on bimanual palpation, to be considerably enlarged. The boy reacted well, and there were no symptoms referable to the pleura or the peritoneum. However, there was no improvement in the general condition. The temperature rose daily to 102° or 103° F. The urine, in spite of diuretics and saline rectal infusions, became still scantier, 14 to 18 ounces in twenty-four hours. It was still clear, acid, and microscopically contained only a few pus cells. Third operation, on March 30, under gas and ether. The old wound was enlarged, and nothing found to account for the temperatures. Owing to the fact that I could feel the right kidney to be more than twice its normal size, and as the left kidney was small and felt normal, I rapidly performed an exploratory nephrotomy on the right side. The kidney was found to be very large. It was drawn into the wound and aspirated in several places, but only blood was withdrawn. The kidney was then split longitudinally; it was found to be normal, and the incision was at once closed with catgut sutures. The left kidney, which was not more than half the size of the right, was then split longitudinally, and was found riddled with small abscesses. The vessels and ureter were secured by two silk ligatures and the kidney cut away. Both the nephrotomy and the nephrectomy were rapidly performed, and there was very little blood lost. Owing to the boy's wretched general condition—he had lost considerable flesh and strength since his admission—it was deemed advisable to give him an intravenous infusion of 24 ounces of saline solution. The examination of the pus from the kidney by Dr. Libman, the assistant pathologist of the hospital, showed only staphylococci, no tubercle bacilli. From sections of the kidney Dr. Mandelbaum, the pathologist of the hospital, diagnosed a (septic) nephritis with miliary abscesses. The boy reacted well from the operation. The first two specimens of urine contained blood; after that none. On the first day after the nephrectomy 18 ounces of urine were passed. On the second day 32 ounces were passed; thus demonstrating nicely the inhibitory action which the diseased kidney had exercised on the healthy one. For nine days after operation the urine contained a trace of albumen, pus cells, and a few hyaline and slightly granular casts. Thereafter recovery was rapid and complete. The boy left the hospital six weeks after the nephrectomy in excellent condition, and has since remained well. In the absence of any other etiological factor, it is fair to assume that the boy had a staphylococcus tonsillitis a few weeks before his admission to the hospital, that this was followed by a staphylococcæmia, and that the abscess in and around the kidney formed the locus minoris resistentia. The enlargement of the right kidney, which took place between the first and the third operations, was a compensatory hypertrophy. When the suppurating kidney was finally removed, the right kidney was fully capable of carrying on the work formerly done by both kidneys.

III. *The indications for nephrectomy during adult life* fall into four classes: (1) Hydronephrosis; (2) Pyelonephritis and pyonephrosis; (3) Tuberculosis; (4) Malignant growths.

I. The indications for nephrectomy for hydronephrosis may be summed up briefly as follows: (*a*) Sacs with obliterated ureters; (*b*) Sacs with little or no kidney tissue remaining; (*c*) Repeated failure of palliative operations, *i. e.* nephropexy, nephrotomy, plastic operations, extraction of stone. Only rarely in the adult will it be necessary to remove a kidney for hydronephrosis.

II. Pyelonephritis and pyonephrosis.—It is well known that kidney infections occur in two different ways: (*a*) as ascending infections; (*b*) as hæmatogenous infections. Ascending infections are much more common in men, as they are generally due to a cystitis, combined with a mechanical obstruction to the outflow of urine from the urethra. This mechanical obstruction is, in the majority of cases, an enlarged prostate or a stricture of the urethra. The ascending infections are particularly common in cases of intermittent hydronephrosis, and in calculous nephritis. The transport of bacteria from one part of the body to another through the blood channels is well known. Ten years ago Israel showed that a suppurative nephritis could be caused by a carbuncle. The same observer has reported an acute suppurative nephritis in an old hydronephrotic kidney as a result of a felon on the finger. Moreover, it must be further borne in mind that not every kidney infection following on the heels of an infection of the lower urinary tract, or following an operative interference on the lower urinary tract, is an ascending process. But here, also, in a certain number of cases, the infection of the kidney takes place through the absorption of bacteria, or their toxins, or both, into the general circulation, and thence their deposit, through the renal artery, in the tissues of the kidney, with the resulting suppuration. The differential diagnosis, in a given case of infected kidney, as to whether the infection is an ascending or hæmatogenous one, is not always possible. In the ascending form, the pelvis of the kidney is regularly affected, and the infection spreads from there through the parenchyma towards the cortex. In the hæmatogenous form the pelvis of the kidney may be perfectly normal, *i. e.* there may be no pyelitis present, but only a nephritis, an infection of the parenchyma of the kidney. But, of course, the process may also affect the pelvis of the kidney, especially secondarily. However, if in a given case we find no infection of the pelvis of the kidney, but only of the parenchyma, then the case is surely one of hæmatogenous, and not an ascending, infection. Case II. is an example of this.

In pyonephrosis the distension of the pelvis of the kidney is not so marked as in hydronephrosis. The pelvis may even be contracted, the distension being in the calyces, which may attain an enormous size. They may be partly or entirely shut off from the pelvis of the kidney by an inflammatory process. In cases of ascending pyonephrosis the ureter is regularly diseased, sometimes distended, sometimes contracted. The ureter usually becomes infected from the bladder. The ureteritis causes a narrowing of the lumen of the ureter; this results in a damming back of urine in the pelvis and calyces of the kidney. The kidney thus becomes distended, a congestion of blood follows, and we now have the best possible medium for the further development of the pathogenic germs that have travelled up the ureter from the bladder. These cases are generally unilateral. If the ascending infection takes place without markedly affecting the ureter, a pyelitis or a pyelonephritis, but not primarily a pyonephrosis, results. Another class of cases of pyonephrosis includes those, in which for a longer or shorter time there has been a passive congestion of urine in the kidney, due to an obstruction in the lower urinary tract—stricture, enlarged prostate, and new growth. Here we may long have a distended kidney without any infection. In these cases the lesion is regularly bilateral. An infection, generally due to the use of the catheter or other instrument, is followed by a double pyonephrosis.

The transformation of a hydronephrosis into a pyonephrosis by a hæmatogenous infection is common. The hæmatogenous infection may originate in an organ remote from the kidney, *e. g.* in an osteomyelitis of the tibia; or, it may originate in a suppurative process of the lower urinary tract. Hence we see that there are two channels through which a patient with an enlarged prostate or a stricture of the urethra can infect his kidneys: (1) By direct continuity, through the bladder and ureter; and (2) Through the general circulation into the renal artery. As movable kidneys are found most frequently in women, it is in women that we most frequently find infected hydronephrosis. And such cases are generally unilateral. In men, on the other hand, where, owing to urethral stricture or prostatic enlargement, the urine is dammed back on both kidneys, we generally find the pyonephrosis to be bilateral.

Regarding the diagnosis of pyonephrosis, we may state that in the early stages the symptoms will be those excited by the cause of the obstruction, calculus, prostate, stricture of urethra, etc. Later on we have, in addition, the symptoms of renal distention and pyelitis, such as lumbar pain, fever, the development of a tumor; sometimes, the evacuation of a large quantity of pus, followed by the decrease in size or disappearance of the tumor. Where there is a periodic evacuation of the contents of such a kidney, the character of the urine improves during the complete retention, while the general symptoms are more marked, and *vice versa.* If the obstruction is not complete, there will be pus constantly present in the urine. The obstruction may be so complete that pus is never found in the urine. Pain may be entirely absent; when present, it is due to distention of the kidney, or to pressure on surrounding organs. Not only should the diagnosis of a tumor be made, but the nature of that tumor determined before operation. Further, the character of the obstruction which has led to the renal distention should be determined. Urethra, prostate, bladder, abdomen and pelvis should be carefully examined. Frequently, by relieving the cause of the obstruction, we will do away with the necessity of directly attacking the kidney.

The surgical treatment of pyelonephritis and pyonephrosis may be summed up in two words, nephrotomy and nephrectomy. It is often difficult to say, in a given case, whether the former or the latter is the better primary operation. If, at the time of operation, nephrotomy seems a more dangerous procedure, owing to the presence of many pockets of pus, which must be opened, thus protracting the operation and causing hemorrhage, then a primary nephrectomy should be resorted to. On the other hand, by doing a preliminary nephrotomy, we give the system an opportunity to get accustomed to the use of only one kidney, as the kidney tissue remaining in the diseased organ readily atrophies after nephrotomy. Then again, we have an opportunity of judging of the functionating capacity of the opposite kidney before attempting to do a nephrectomy. As a matter of fact, we do not, after such a secondary nephrectomy, find such a marked disturbance in the urinary excretion as we do in cases of primary removal of a kidney. Moreover, the remote results of a nephrotomy may be bad in conducing to the development of sepsis; or a renal fistula may remain, and finally necessitate the removal of the kidney.

Case III.—Max G., forty years old, admitted to Dr. Lilienthal's service at Mount Sinai Hospital, August 28, 1901. Patient stated that his mother had died of nephritis; the family history otherwise was negative.

Past history.—Father of three children; wife never aborted. Admitted having had two attacks of gonorrhœa; denied syphilis. Had an attack of typhoid fever fifteen years before, at the age of twenty-five years. Following this he was well for ten years. Five years before admission patient had had an attack of intense pain in the left loin. The pain had radiated downwards towards the inner part of Poupart's ligament, and also towards the greater trochanter. This attack had been accompanied by painful and bloody urination. After two weeks of almost continuous pain he had passed a small stone per urethram. During eight months following this attack, with the exception of a little pain in the left side, the man had been perfectly well. He had then had a second attack similar to the first, though less severe; and, in place of passing a stone, he had passed gravel. Hæmaturia was not noticed during that attack. During the four years following the second attack, patient had had six other attacks. They were all similar to the first attack, but there had been no blood or pus noticed in the urine. The last attack had occurred two weeks prior to his admission to the hospital, when patient had passed a small stone, which he brought with him to the hospital. Appetite had been poor; bowels somewhat constipated. Patient stated that he had lost some flesh, and that the attacks of pain had been of such frequent occurrence that he was incapacitated for work.

Physical examination showed a fairly well-nourished man. The tongue was moist and coated. Heart and lungs were normal. There was tenderness over the left kidney, on deep palpation. The prostate and both seminal vesicles were slightly enlarged. The urine was alkaline, 1020, contained neither albumin nor sugar, but a moderate number of pus cells and many triple phosphates. Operation, on August 31, 1901, under gas and ether. I made an incision parallel to and just below the free border of the ribs on the left side, beginning at the anterior margin of the quadratus lumborum, and extending forward to the peritoneal reflection. The perirenal fat was incised, and the palpating finger detected a large kidney, extending so far upward that it was at first thought it might be the spleen. At its lower pole the kidney was freed with some difficulty, owing to adhesion to the capsule. The organ was too large to be delivered through the original incision, which was enlarged anteriorly without opening the peritoneum. The kidney was then drawn into the wound. It was dark red, friable and showed several areas of loss of substance on its surface, where the capsule had been adherent. The vessels were grasped at the pelvis by an assistant, and the kidney was split just posterior to its convex border; hemorrhage was quite free. Some pus escaped from the pelvis of the kidney, but the examining finger could detect no stone. A drainage tube was introduced, and the rest of the kidney wound was sutured with catgut. Packings were placed around the kidney on account of the oozing from adhesions. Following the operation the patient developed a diffuse bronchitis with signs of consolidation over the base of the left lung. The consolidation cleared up quickly, but the bronchitis continued. During the first week after operation the amount of urine varied from 29 to 42 ounces in twenty-four hours. There was no hæmaturia after the second day. The urine contained a trace of albumin, 1 per cent. urea and no casts. On September 19 the tube was removed from the kidney and a small piece of kidney tissue excised for microscopical examination. Urine collected from the tube before its removal from the kidney, was cloudy, 1022, contained albumin, no sugar, 1 per cent. urea, no casts, a few pus cells, detritus, calcium oxalate and triple phosphates. On September 25 there was a sudden rise of temperature to 103°. The section from the kidney was pronounced a chronic inflammatory process by Dr. Mandlebaum, the pathologist of the hospital. As the condition of the patient had not improved during the four weeks following the nephrotomy, as the temperature had persisted in rising daily to 101° or 102°, and as the patient was steadily losing ground, I determined to remove the kidney.

September 28.—Nephrectomy under nitrous oxide anæsthesia. Owing to the diffuse bronchitis which had persisted, it was deemed unsafe to give ether or chloroform. The old incision was reopened under eucaine; the adhesions were broken up, and the hemorrhage checked by packings. Nitrous oxide was then administered, and the kidney, which was high up under the ribs, was delivered into the wound with some difficulty. As there was no heavy silk on hand, a medium-sized silk ligature was used double to tie off the pedicle. Doubling the ligature interfered with tying as firmly as was desired; and, when the kidney was cut away, the ligature slipped off. The vessels were at once grasped with several clamps. Owing to the extreme friability of the vessels, the hemorrhage was considerable. Several clamps were replaced by ligatures, and four clamps were left *in situ*. The wound was packed with gauze. The patient stood the operation, which lasted forty minutes, extremely well. His pulse was of such good quality that no infusion was deemed necessary. Examination of the kidney showed the whole organ to be enlarged, completely degenerated in spots, and most of the markings obliterated. From the microscopical examination, Dr. Mandlebaum reported a typical pyelonephritis. During the first week after the nephrectomy 19 to 29 ounces of urine were passed daily. The urine was acid, 1010, contained a faint trace of albumin, no sugar, urea 1.5 per cent., a few pus cells and triple phosphates. The clamps were removed forty-eight hours after operation, there was no hemorrhage. On November 1 the wound was almost healed, excepting at one point, where there was a communication with the ureter. Methylene blue solution injected into this opening appeared in the urine in fifteen minutes. A few pus cells were still present in the urine, which otherwise was normal. On November 17 the patient left the hospital. He had gained twenty pounds in weight, and there was only a very slight discharge from the wound, which soon healed completely.

3. Kidney tuberculosis.—As I pointed out in a former paper*, hæmaturia is often the earliest symptom of the disease, and the blood is intimately mixed with the urine. The disease is commonest in women between twenty and forty years. It is usually unilateral. It may remain latent for months or years, and there may be no symptoms until the bladder becomes diseased. According to Israel, ascending renal tuberculosis is found much oftener in men than in women. The combination of genital tuberculosis and tuberculosis of the urinary tract is common in men, and never occurs in women, at least there is only one such case on record. In a large percentage of operated cases the bladder is found involved. The earlier the diagnosis of renal tuberculosis is made, the less likely is the bladder to be effected. A moderate involvement of the bladder does not constitute a contraindication for nephrectomy. It has been estimated that in only 9 per cent. of cases of renal tuberculosis is the disease bilateral, and in the great majority of cases the second kidney does not become affected until long after the first. The symptoms to which the disease may give rise have been well summed up by Morris as lumbar pain, polyuria, pyuria with acid urine, hæmaturia with acid urine, frequent nocturnal, as well as diurnal, micturition, tubercle bacilli in the urine and the general symptoms of tuberculosis. In the early stages the differential diagnosis from renal calculus is often very difficult. For the differential diagnosis I would refer to my previous paper. The bladder symptoms are sometimes the earliest and most pronounced. The cystoscope will sometimes show an area of congestion around the mouth of the ureter on the affected side. This together with the presence of an enlarged kidney, and of pain in one loin, will aid greatly in determining the side that is affected. According to Morris, "if there is intermittent pyuria with increase in dullness, pain or tumor when the pus ceases to be present in the urine there is not only a further indication of the organ involved, but good proof that the other organ is not affected."

4. New growths of the kidney.—In the adult they are found most frequently after the fortieth year. As we have just seen, this is in contrast to tuberculosis of the kidney, which is most common between twenty and forty years. The new growth is usually a sarcoma or a carcinoma. The characteristic points about renal tumors are: (*a*) Large intestine is anterior to the tumor. On the right side the colon is usually anterior and to the inner side of the tumor. On the left side the colon is anterior and to the outer side. This distinguishes a renal tumor from one of splenic or hepatic origin. (*b*) Renal tumors grow forward, while abscesses generally point backward. (*c*) Renal tumors do not descend as much on deep inspiration as do tumors of the spleen or liver.

The three cardinal symptoms are hæmaturia, tumor and pain. The character of the hæmaturia was discussed at length in my former paper, as was also the difference between the hemorrhage due to renal stone, tuberculosis and new growth. The question as to whether a tumor in a given case is operable or not, is of great importance. Much will depend on the length of duration of the symptoms; the mobility of the tumor, the presence of œdema in the loin, or in the leg on the affected side; the presence of enlarged glands, which can be felt within the abdomen, or along the brim of the pelvis. A careful examination of all the organs in the body (especially the lower urinary tract) should be made for signs of secondary new growths. The improvement in the operative results following nephrectomy for new growths has gone hand in hand with the improvement in other branches of kidney surgery. The mortality has fallen from 60 per cent. of all cases operated on prior to 1890 to 20 per cent. in 1899.

To discuss at length the rarer indications for nephrectomy, such as chronic nephritis with hæmaturia, cysts of the kidney, wounds, contusions, lacerations and urinary fistulæ, is beyond the limits of this paper, which deals avowedly only with the common indications for the surgical removal of the kidney.

* "Blood in the Urine as a Symptom and the Diagnosis of Its Source." *New York Medical Journal*, March 9, 1901.

In conclusion we would say that the brilliant advances made in kidney surgery in the past decade are due not only to improvement in the technique of bladder and ureter examinations, and of operative work, but also to the hearty coöperation of the internist, who, in the majority of cases, sees the patient before he comes into the hands of the surgeon. It is largely due to his methods in making an early diagnosis that kidney surgery has advanced to its present position. And we venture to predict that the future of kidney surgery will be made still brighter by progress along the line of still earlier diagnosis of the surgical diseases of the kidney. The rôle that the cystoscope and the freezing point of the blood and urine are to play will, we believe, be an important one.

RESECTION OF THE CERVICAL SYMPATHETIC GANGLIA IN GLAUCOMA; ITS PRESENT STATUS.*

By WILBUR B. MARPLE, M.D.,
NEW YORK.

It is well understood that the treatment of many cases of glaucoma is most unsatisfactory, and that, notwithstanding all our skilfully-directed therapeutic measures, in a considerable percentage of cases (some estimate as high as 50 per cent.) no improvement in vision is effected; while from 10 to 25 per cent. of the cases, according to different writers, end in entire blindness. One can appreciate, therefore, how welcome to the ophthalmic surgeon would be any effective addition to the therapeutic resources at his command in the treatment of this disease.

As long ago as 1866, Wegner (*Graefe's Archives*, '66, II., p. 1) published a series of experiments on rabbits, from which he considered that section of the cervical sympathetic was followed by decrease of the intraocular tension and contracted pupil, and in 1897 Abadie, reasoning from the results of these and other experiments, recommended section of the cervical sympathetic as a means of treatment in glaucoma. It was, however, Jomesco of Buckaross who, in September, 1897, resorted to the operation for glaucoma, although it had been done several times previously by others, for other conditions, such as epilepsy, exophthalmic goiter, etc. Since 1897 the operation of resection of the cervical sympathetic has been done in about eighty-six cases, for glaucoma. Ziehe, in 1900, collected seventy-four cases, and the writer has found twelve others, several not yet published, and it may be of interest, certainly it is of great importance, to consider its claims as a legitimate operation.

The method of operating has been already frequently described in previous reports. Most recent operators go in back of the sternocleidomastoid muscle, and content themselves with a removal of the superior ganglion, instead of taking away all three, as Jomesco originally did. In the hands of a skilful surgeon of experience the operation is not one of great difficulty, nor is it a bloody one. Careful dissection is necessary on account of the proximity of important vascular and nervous structures. It was predicted that the operation would have disastrous consequences, as well upon the general condition of the patient as upon the nutrition of the eye, but these prophecies have not been realized. Abario (seventeenth annual meeting of the French Ophthalmological Society, Paris, 1899) stated that he had seen intraocular hemorrhage follow resection of the sympathetic in animals, and Doyon reported (Société de Sc. Médicale du Lyons, 1896) that he had seen the operation followed in rabbits by cataract. But Hertel (v. *Graefe's Archives*, '99, 2) reports his observations on the results of extirpation of the ganglion in young animals, some of them observed for over a year, and he has never observed any such complications. In his hands resection has had no injurious effects, either upon the growth or upon the nutrition of the eye. Neither cataract nor intraocular hemorrhage has been reported as following the operation upon any human subject. Paralytic effects are ptosis, some exophthalmus, ocular and nasal injection and hypersecretion, and often increased temperature of the same side of the head. The ocular and nasal injection usually disappears quite early, and enophthalmus diminishes gradually. Ptosis may disappear, but in many pain it continued as long as the patient was under observation though often to a less marked degree than immediately after the operation. Pain or difficulty in swallowing has been occasionally observed, but this symptom has usually disappeared early. An accidental complication due probably to section of the recurrent laryngeal nerve has been hoarseness amounting at times almost to aphonia. In one case of Mohr's there was slight motor disturbance of the right arm. The operation can, therefore, be regarded as a relatively harmless one, which as yet (in the cases operated on for glaucoma) has not injured either the eye or the general health of any patient. In other words if it does no good it can safely be said that it does no harm. If the bilateral operation is to be performed resection should be done first on one side, and after an interval of several days or weeks it can be done on the other side. Fatal results have been reported when ablation of the ganglia on both sides has been performed at one operation, as was not infrequently done formerly when the operation was resorted to for epilepsy, exophthalmic goiter, etc.

---

*Read before the New York State Medical Association.

What then are the benefits claimed for sympathectomy in glaucoma? These are first a diminution of the intraocular tension, and, as a result of this hypotony, improvement of vision, widening of the visual fields, and relief of pain. It will be of little advantage to consider at length either the theoretical explanations of the modus operandi of the operation, or the theoretical objections to it, as Mohr says, "the theory of Abadie and Jamesco that glaucoma is caused by an irritation of the vaso-dilator filaments of the cervical sympathetic belongs in the domain of speculation." To decide fairly just what the operation has accomplished, and in what forms of glaucoma, if in any, it is indicated, is a matter of the greatest difficulty, notwithstanding the number of cases in which it has been employed. Most observers have suggested the operation as especially indicated in simple glaucoma an essentially chronic disease, and yet details of cases have been published which have been observed only a few days after the operation! Jomesco published, in May, 1899, in the *Centralblatt fur Chirurgie*, an account of eight cases, which report was almost identically the same as he had published in *La Presse Medical*, in June, 1898. Although these reports were almost entirely the same, and although a year had elapsed since the first publication, the later one gives us absolutely no new information as to the final outcome of the cases, and in five out of the eight cases nothing is stated in either report as to how long the patients were under observation. Yet upon such clinical studies does Jomesco base his very important conclusions.

It is not so much more cases that are needed as that those which have been already operated upon shall be kept under longer and more careful observation so that we shall be able to decide just what are the permanent results. What has been said by Dr. Knapp in reference to the removal of the lens in myopia is equally true in reference to the operation of sympathectomy in glaucoma, for we will not be able to reach a just conclusion as to its value on indications until its "boom" is over—until operators are less interested in getting their cases immediately into print, and more interested in accurate and long-continued observation of their patients. In some cases the process has been reported as "remaining stationary" after the operation. But, as Augelucci asks, how are we to know, unless we keep our patients under observation a long time, whether this stationary condition is a result of the operation or simply a phase of the disease? Among all the cases the writer has found, only about 20 per cent. of them had been under observation for one year or more. To draw positive conclusions, therefore, from such material is a difficult if not impossible task. The operation has been done in acute and subacute inflammatory glaucoma (seven cases), in chronic inflammatory or irritative glaucoma (eighteen cases), in simple chronic glaucoma (thirty cases), in absolute glaucoma (eleven cases), and in hydrophthalmus (four cases). There can be no question that in a considerable number of them the operation has been followed for a time by diminution of tension and contracted pupil, and later by increase in the size of the visual fields, less frequently by improvement in vision. At the Heidelberg Congress, in 1900 (*Klinische Monatsblatt fur Augenheilk.*, 1900, p. 679), Grunert reported that, out of sixty-two cases collected, there was improvement in forty, in thirteen the condition was unchanged, and in nine it was worse. But in a considerable number of cases improvement meant merely relief to pain, or diminution in tension, and a large majority of the cases had been under observation only for a short time. Abadie, in the Paris Congress of 1900, considered the indication to be glaucoma simply where, notwithstanding the use of the myotics, the condition becomes worse. He also regarded it as a means of relieving pain in absolute glaucoma. That it cannot always be relied upon to do this is shown by a case of Grunert's (*Klinische Monatsblatt fur Augenh.*, 1900, p. 250). The patient, a female, aged sixty-seven years, suffered intense pain from chronic inflammatory glaucoma absolution, and was treated unsuccessfully for a few days with myotics, then ablation of the cervical sympathetic was performed. The pain was less for a few days, but soon returned in great severity, so that the patient begged to have the eye removed, which was done eight days after the sympathectomy. Jomesco at the International Congress at Paris, in 1900, recommended the operation in simple chronic glaucoma, in which inflammation or irritation is not present, that is to say, in the class of cases where iridectomy accomplishes so little. At the same meeting Axenfeld, from an experience in five cases on three individuals, says that it is indicated: (1) If an iridectomy has resulted badly in the first eye; and (2) If the field is very much contracted, so that little is to be expected from an iridectomy. With these restrictions he considers the operation as a justifiable experimental attempt, which may possibly be extended to the malignant cases of hydrophthalmus. In glaucoma simplex he prefers to do an iridectomy first, for in some of the cases reported glaucomatous attacks have occurred after resection, and required an iridectomy, which has then to be done under abnormal vascular conditions. He probably bases this latter opinion upon the following case of Mohr's (*Klinische Monatsblatt fur Augenh.* 1900 p. 150). The patient suffered from simple chronic glaucoma. Resection of the sympathetic ganglion was followed by improvement in vision and widening of visual fields. This marked improvement continued for two and a half months, when acute glaucomatous symptoms developed with intense pain, and iridectomy was resorted to. After completion of the section the iris protruded, and it was followed by the lens and then by all the contents of the globe, with abundant hemorrhage and loss of the eye, ending in phthisis bulbi. Such a case emphasizes the importance of making a guarded prognosis in these cases, even where the immediate results are brilliant. Whether the inflammatory glaucomatous attacks which have been observed a few times after extirpation in a previously simple glaucoma were the result of the extirpation, it is impossible to say.

There have been several brilliant results reported as following soon after the operation. Among them some from the Tübingen clinic, observed by Mohr and Grunert; others by Demicheri of Montevideo. In one case of Mohr's, reported in the article quoted above, but which was observed only three months, the vision increased from 5-12 to 5-6, and the patient returned to his work. But Mohr himself recognizes the necessity of observing this case much longer before drawing any conclusions from it. In one of Demicheri's cases vision went from counting fingers or 1m. to vision of ⅔, but this case was under observation only two months. Recently, at a meeting of the Section on Ophthalmology of the New York Academy of Medicine (November 18, 1901), Dr. Colman W. Cutler reported a case of chronic simple glaucoma, which he had had under observation for several years, and in which, notwithstanding an iridectomy, the vision had fallen to 20-200. Resection of the sympathetic ganglion was done early in June, 1901, and soon afterwards the vision improved to 20-40 and has remained so for six months. The result in Dr. Cutler's case is brilliant if it will only last. but it is significant that a similar *temporary* improvement in vision was noted after the iridectomy, which was done some time before, and the optic nerve shows a deep glaucomatous excavation. Still, as Dr. Cutler remarked, even if the visual improvement is not permanent and even if the patient should again become as nearly blind as he was formerly, or more so, nevertheless he felt that to give the patient such visual improvement for six months or a year, if no longer, was a good and sufficient reason for having done the operation.

As to the permanence of the results, Panas quotes Jabauloy (*France Medical*, 1897, p. 5), who had employed sympathectomy in exophthalmic goiter, as follows: "The effects of sympathectomy often last only two or three months. At the end of this time substitution is established by the sympathetic filaments of the trigeminal and pneumogastric nerves and relapses occur." Panas saw a case in his clinic of simple chronic glaucoma, in which double ablation had been done three months before. Nothwithstanding this, vision had failed, one of the eyes had become hard and more amblyopic, and the visual fields had contracted. He thinks that the diminished tension is only temporary, and that, after a relatively short time, the tension increases again and only the myosis persists; that the immediate results are not the permanent results. Albertotti of Modena reports (Annal. di Attalm, 1900), five bilateral operations in simple chronic glaucoma very carefully observed for many months (three cases were under observation fifteen months). In none was the progressive loss of sight prevented, although in two or three pain did not recur. From his experience he thinks resection cannot take the place of iridectomy, but that it can be employed in those cases where iridectomy is refused.

In a recent letter to the writer from Dr. Ball of St. Louis, who has done the operation in three cases of glaucoma, he says, "while the immediate results are sometimes brilliant, the ultimate results are only fair."

Ziehe (Vassius' Sammlung aus dem Gebiete der Augenheilk., IV. Band, Heft 1 and 2) gives the literature of seventy-four cases, and the writer has found twelve additional cases, from which the two following tables have been compiled. Table No. 1 includes the cases observed for one year or more; Table No. 2 comprises those cases observed less than one year, many of them only a few weeks. In these two tables he has not included the three cases of Herbert, one of Schoen, and one of Dodd, inasmuch as the description of these cases is too incomplete. Neither has he included the four cases of Albertotti, where the operation was employed as a means of prophylaxis for the second eye.

TABLE I. (Observed One Year or More.)

	No.	Improvement at first; subsequent relapse.	Improved.	Improvement limited to relief of pain or diminution of tension.	Unchanged.	Worse.
Acute Inflammatory (Irritative)	2			2		
Hæmorrhagic..........	1			1		
Chronic Inflammatory (Irritative)..........	2		1	1		
Simple Chronic.........	6	3	2		1	
Absolute...............	2	2				
Total.............	13	5	3	4	1	

TABLE II. (Observed Less than One Year.)

Acute Inflammatory....	3		1	2		
Subacute Inflammatory.	1	1				
Chronic Inflammatory (Irritative)..........	16	1	7	5	3	
Chronic Inflammatory (Absolute)	4		1	1	1	1
Simple Chronic.........	24	5	8	6	5	
Simple Chronic(Absolute)	5		1	2	2	
Hydrophthalmus.......	4				4	
Total...........	57	7	18	16	15	1

It will thus be seen that only thirteen cases (less than 20 per cent.) have been observed long enough to make them in any way the basis of any deductions, while fifty-seven cases have been under observation for only a comparatively short time. The writer is indebted to Dr. G. F. Suker of Chicago for his courtesy in giving him the results in his four cases, some of them not yet published.

The apparent discrepancy between the writer's total of seventy cases and what it would be if the twelve additional cases, which he has collected, were added to Ziehe's seventy-four (viz., eighty-six cases) is explained by the fact that he has counted patients, and Ziehe operations. That is, Ziehe counts a bilateral operation on one patient as two, and the writer as one. Further, by the fact that he has omitted nine cases for reasons stated above.

The cases not referred to by Ziehe are:

1. Black, *Ophthalmic Record.* March, 1901, p. 150.
2. Coover, *Ophthalmic Record.* March, 1901, p. 152.
3. Mullen, *American Medicine.* March, 1901, I., p. 552.
4. Ball, unpublished case.
5. Kipp "Translations American Ophthalmic Society, 1901."
6. Gruening, New York Academy of Medicine, (Oph. Sec.). November 18, 1901.

7–8. Cattoneo, "Bulletin de Sc. Med., Bologna," 1900, p. 526.

9. Cutler, New York Academy of Medicine (Oph. Sec.). November 18, 1901.

10, 11, 12. Suker.

It is interesting in this connection to read part of a recent letter from Dr. George J. Bull of Paris (*Ophthalmic Record*, August, 1901, p. 447). He says: "During the debate before the French Congress of Ophthalmology in May of this year on de Wecker's report on the value of iridectomy in glaucoma, Dr. Émile Javal, now totally blind in both eyes from glaucoma, was led into the room by a servant and took one of the front seats. One speaker after another expressed his opinion on the subject only to show that little is known with certainty and that we have to do with a disease which is far from being properly understood. At length Javal was called upon to speak and not rising as did the other speakers he turned in his chair towards the center of the room and began his remarks in a low tone. The men in the farther part of the room stood up and came nearer, the better to see Javal and hear him, and presently all were standing except the speaker and those in the few seats around him. It was a dramatic scene not to be forgotten, the sightless speaker his eyes covered with dark-blue spectacles, his neck scarred from an operation to excise the sympathetic ganglion a wounded soldier indeed and the older men in the group around him, with the younger men beyond bending forward the better to hear the soldier's story. From time to time Javal ceased to speak, but no one broke the silence for it was seen that he was reading with his fingers the notes he held on the table."

To sum up briefly it may be said:

1. That the operation of extirpation of the sympathetic ganglion is a safe procedure in the hands of a skilful surgeon.

2. That (as Ziehe says), while the material is not yet sufficient to reach a positive conclusion as to the permanence of its effect, it is nevertheless established that some of the glaucomatous cases have been improved for some months by resection, in others the condition apparently remains stationary. The results have varied, and one cannot yet be sure in what cases it can be advantageously employed. It at least, apparently, does no harm. A considerable number of favorable results have been reported in chronic irritation or inflammatory glaucoma, as well as in simple glaucoma, in which oftentimes pain is abolished.

3. It does not replace iridectomy, but may possibly supplement the latter, in case this is refused or has already resulted disastrously in the other eye, or is contraindicated, as in hemorrhagic glaucoma, dacryo-cystitis, etc.

4. Until our cases are observed more carefully and for a longer period of time, it will be impossible to arrive at positive conclusions as to the indications for the operation, or as to its permanent results.

35 West Fifty-third Street.

Cyclic Albuminuria.—Wm. E. Huger draws attention to the fact that position is the most powerful factor in influencing the albumin. In all cases, albumin disappears from the urine soon after lying down and reappears after arising no matter how the hours are changed or how long the patients lie down. Drugs do not affect the disease. Continued rest in bed should always be urged, because, at any rate, it removes the exciting cause. The writer believes that on a *very careful* examination for casts a large percentage of cases will be found to contain them, and that the serious prognosis given because of their presence will be modified. He concludes that cyclic albuminuria, like the recognized pathological albuminuria, is due to one or perhaps all of the following causes: (1) Inflammatory and degenerative changes in renal structure, as evidenced by the finding of casts, and there is every reason to think that by careful searching casts will be found far more often than previous reports lead us to believe. (2) Alterations in the quality of the blood which render its serum-albumin more diffusible; there is nothing to prove an inferior diffusibility in these cases, but the patients are almost always anæmic; (3) Alterations in the degree of blood-pressure here due to a mechanically increased pressure on the renal veins. It has been observed that occasionally these cyclic cases pass into Bright's disease, but that by far the majority have ended in recovery, and that many of the patients have been followed for years and then lost sight of still in the same condition.—*Bulletin of the Johns Hopkins Hospital*, April, 1902.

A Case of Transposition of One Viscus Only.—Edward H. Thomas reports the case of a woman of twenty years who consulted him in regard to a swelling in her abdomen on her right side, which, in four months from the time she first noticed it, had increased and occupied a little more than half the abdomen. The woman had fever of a distinctly malarial type, and was anæmic. The tumor occupied the right lumbar, right iliac, part of the umbilical, and part of the hypogastric regions. It had no connection with the liver, which could be clearly mapped out by percussion on the right side. The region of the spleen was empty altogether, and very careful percussion and palpation failed to show any splenic dulness in the left hypochondriac region. The right border of the tumor could be felt extending quarter of an inch beyond the middle line of the abdomen toward the left, and it was notched and somewhat rounded. The heart was in its normal position. The diagnosis of the tumor was certain, viz., transposed hypertrophied spleen. The diagnosis was confirmed by the result of anti-malarial treatment, both local and internal, which considerably reduced the tumor within the month that the patient was under the writer's care.—*Indian Medical Record.*

The Rheumatic Affections of Childhood.—J. Burnet includes, under this heading, endocarditis, cardiac dilatation, subcutaneous tendinous nodules, tonsillitis, acute pleurisy and pneumonia, appendicitis (in certain instances), anæmia, stiff-neck and gastro-enteric spasm. He says that the children of rheumatic parentage do not always show some definite manifestation of the disease, but close observation will often show them to be bad-tempered, irritable, nervous, afraid of the dark, sensitive, often thin and spare, frequently complaining of headache and, generally, are of a restless disposition, constantly on the move after some fresh form of amusement. When this nervous restlessness reaches a certain point it becomes associated with muscular movement, and then we have the well-known condition of chorea established. This is the true origin and evolution-history of an attack of chorea. It is muscular movement superadded to a pre-existing nervous unrest.—*Medical Times and Hospital Gazette.*

Early Treatment of Acute Inflammation of the Middle Ear.—E. L. Meierhof says that experience has taught him that in nearly every case early treatment, of which free incision of the drumhead is the most important feature, relieves pain both spontaneous and induced, and in children should be followed by reduction of temperature even if the exudate is only serous. We should anticipate rupture by incision and thus prevent perforations so situated that drainage will be insufficient. Timely incision prevents chronic suppuration. As regards paracentesis, it is a safe rule when in doubt, to incise, especially so in the exanthemata. This, however, is not necessary when the drumhead presents only a few streaks of redness, provided the view is good and the patient can be kept under close observation.—*Annals of Otology.*

Some Observations on the Recognition and Treatment of Trachoma of the Female Genital Tract.—J. A. Hale believes in the existence of a vaginal condition similar in pathological essence to trachoma of the eye. He regards the following symptoms and physical conditions as the clinical expression of the malady: A thin, watery discharge, no history of specific infection, the peculiar rice-grain surface of the mucosa from enlarged papillæ and bleeding fissures, persistent vaginismus, increasing constitutional nervousness from peripheral nerve involvement in the new tissue formation of denuded surface, and in well-developed cases, cicatricial formation, oftentimes demanding surgical interference.—*The Medical Fortnightly.*

New York, May 10, 1902.

THE SUTURE OF ARTERIES.

THE question of the possibility of suturing a wounded arterial trunk without interfering with the potency of the vessel is a recent one in surgical literature, but it is already responsible for the presence of considerable discussion in the journals. A point, however, which does not, in this connection, seem to have attracted much attention is that of advisability. Experience has established the fact that it is possible to suture successfully almost any artery that is not too small to be manipulated, but whether this is worth the trouble is, in many instances, doubtful.

In the *Boston Medical and Surgical Journal*, March 27, 1902, Hubbard reviews much of what has been written on this subject, and describes what is considered the best technique. The first point to be attended to is control of circulation, as of hemorrhage, if the vessel has been injured accidentally. The point at which the blood current is to be interrupted must be some distance from the site of the suturing, and the pressure must not be so great as to cause any bruising of the walls of the vessel. If a resection is to be done the point of control must be some distance from the operative field and must be especially secure. It is necessary to use the smallest round needles which can be handled and the suture material must be of a size sufficiently large to fill completely the hole left by the needle in the arterial wall. Whether the suture is to be continuous or interrupted will depend upon the nature and extent of the wound which is to be closed. Fine silk is apparently the material which is generally considered most desirable, though it would seem that properly prepared cat-gut possesses many advantages which might make it more desirable. When the suturing is completed it is desirable to test its efficiency by removing the compression from the distal portion of the artery, thus allowing the blood to flow in under low pressure. Any leakage can be controlled by slight pressure or one or two extra sutures.

The results so far have shown that it is perfectly feasible to suture successfully the wounded arterial wall in the same way as has been shown to be successful for the walls of veins, but whether in most cases it is worth while is another question. The ease with which the arterial anastomotic circulation is established after obstruction of the main channel is too well known to need description, and a successful result, after the various forms of ligation of arteries, is practically certain, except in the case of a few of the largest vessels, so that, at least for the vessels of the extremities, it seems very doubtful whether it is worth while to apply an intricate suture when the simpler operation of ligation accomplishes all practical good results. In the case of some of the largest arteries, or in the presence of certain pathological conditions, the question of suturing may assume more importance, and the use of a suture might be thought more desirable than ligation. It is hardly necessary to say that when one of the large arteries of the trunk is wounded there is no time for attempting a complex operation, except possibly in a few unusual instances. We do not wish to seem to depreciate an advance or a refinement in surgery, but desire merely to emphasize the fact that utility, security for the patient, and certainty of outcome are of greater importance than mechanical ingenuity and elegance, and we think that, in most cases, of wounded or diseased arteries, the best results will be attained by ligature, rather than by the more complicated suture.

In arteries the pathological conditions with which we most often have to deal is, of course, aneurysm, and whether there may not be a field of usefulness here for arterial suture is, perhaps, worth discussion. At present our chief and ultimate form of treatment is by means of some form of ligature, and in many instances this has proved very satisfactory, though in a certain proportion of cases it is inapplicable or unsatisfactory. The forms of treatment of aneurysm, other than ligature of the artery in its continuity, have for their aim obliteration of the sac by exciting coagulation of contents or adhesion of the interior surfaces, completely or in part. It is possible that some sort of suturing operation might, in cases in which the aneurysmal sac has not become too greatly thinned, be undertaken successfully, and an important means of coping with a serious condition thereby added to our resources. Under normal circumstances considerable dependence is placed upon the power of rapid adhesive union which the lining endothelium of the artery has, but it is by no means certain that we could count upon this to a very great extent under the altered conditions in the interior of an aneurysm. It is probable that in most cases ligation will remain our chief dependence in the operative treatment of aneurysm, but, apparently, there may be some cases in which a suturing operation, combined with temporary partial control of blood current, might be of great service. A plan somewhat like a reversed gastroplication might offer a feasible solution of the question. Occasionally operators are unfortunate enough to wound an artery of vital importance during the course of an operation, and under such conditions, where there is an opportunity to control immediate hemorrhage, an arterial suture might be of great value. It is safe to say, however, that arterial suture is a procedure which will be found useful only in rare instances and under exceptional circumstances, though the demonstration of its feasibility is of some interest.

New Health Officer in Richmond.—The Board of Health has appointed Dr. John T. Sprague to succeed the late Dr. Theodore Walser as Assistant Sanitary Superintendent of the borough of Richmond. The salary is $3,500 a year. Dr. Sprague had been a medical school inspector for a number of years.

COMPLICATIONS ATTENDING DYSENTERY

Dr. Charles F. Craig, U.S.A., Director of the Laboratory at Presidio Army Hospital, draws attention in the report of that institution for 1901 to the complications observed at autopsy in cases of dysentery.

The complications attending this disease have received scant notice at the hands of writers on the subject, and therefore the knowledge gained by Dr. Craig in several [illegible] autopsies on patients who died from dysentery at Presidio should be of especial and somewhat peculiar value.

The brain in nearly every case in which it was examined (thirty-two) showed an increase in the amount of cerebrospinal fluid. Often this increase was very extensive, the brain being oedematous. In all the cases of amebic dysentery the blood vessels of the cerebrum were very much congested, and in about one-half of the cases small capillary hemorrhages had occurred. In all the cases of follicular dysentery the outer surface of the cerebrum was anæmic in appearance, while in the diphtheritic and gangrenous forms the surface was as a rule congested.

The most common conditions found complicating dysentery in the lungs, were oedema and bronchopneumonia. Another very common condition is chronic pleurisy, which was found in sixteen cases. Lobar pneumonia occurred in four cases, and was the cause of death of all. Chronic bronchitis occurred in five cases, acute bronchitis in one case, acute pleurisy in one case, infarcts of lung in two cases, and pulmonary tuberculosis in three cases. Empyema was found in two cases, both due to a rupture of liver abscess into the pleural cavity. Metastatic abscesses of the lung were found in both cases of gangrenous dysentery, and in both cases was associated with abscess of the spleen and kidney. The two most frequent complications in the respiratory system were hypostasis and bronchopneumonia, and these are also the two which would be the most likely to occur owing to the weakness and recumbent posture of the patient. Complications of the circulatory system.—In fifty-one of the cases the amount of fluid in the pericardial cavity was markedly increased. This oedema of the pericardium is one of the most characteristic complications observed in the fatal cases of dysentery. Acute pericarditis was observed in five cases, but in none were any of the complications present due to the heart. Complications of the genitourinary system.

Some form of inflammation of the kidney was present in almost every case of dysentery which came to autopsy. Out of seventy-three cases sixty-three showed some form of nephritis. Of the varieties of the inflammation of the kidney—acute tubular nephritis was the most common, thirty-two of the sixty-three cases being caused by this variety. Next in frequency comes the subacute parenchymatous form, which furnishes twenty-six of the cases. The remaining five were due to chronic interstitial nephritis. In such cases there was a history of alcoholism, which probably accounted for the character of the complication.

The most common complication found in the liver was fatty degeneration, which was present in thirty-five of the cases, venous congestion was present in twenty-one cases, cirrhosis of the liver in four cases, metastatic abscess of that organ in two cases and amebic abscess in nine cases. Cirrhosis of the spleen was found in twenty-nine cases, infarcts, two, and abscess in four cases.

Chronic enteritis almost invariably accompanied the dysenteric process. Of the seventy-three cases fifty-four showed a marked chronic enteritis, while ten of the remaining showed some inflammation of the small intestines but not marked enough to class as a distinct enteritis. Chronic gastritis was present in thirty-eight cases. Perforation of the intestine due to dysenteric ulcerations in four cases, and acute peritonitis was found in seven cases.

The most serious complications are most frequent in the severer forms of the dysenteric process, as, for instance, in the diphtheritic, gangrenous, and amebic types, while they are the least common in the follicular form, which is also the least severe from a pathological standpoint.

Dr. Craig truly says, "From the study of the complications which attend dysentery it will be seen how numerous and important they are. It is not too much to say that in a large proportion of the cases which resulted fatally, death was due more to the complications than to the dysenteric affection." There is much need of a more accurate knowledge as to the prevention and treatment of dysentery, and the opportunities afforded our army surgeons in tropical regions will, it is certain, be seized upon to demonstrate more clearly the proper line of treatment to be followed in this disease, and to settle once and for all time the position of ipecacuana as a therapeutic remedy for dysentery.

Old-Fashioned Remedies

In the rural districts of Europe and of Great Britain, superstition still lingers, and in those places where education has not dispelled the mists of ignorance the simple country people retain a touching belief in the remedies used by their ancestors. This is especially the case in Ireland—that part of England known as Wessex—and in the Eastern counties, whence came the majority of the early New England settlers.

In certain portions of France, too, the peasantry have an abiding faith in tisanes and herb mixtures of various kinds.

The Spectator, April 12, has an article telling of the love of the English agricultural laborer for dosing himself, and recounting some of the extraordinary concoctions he is in the habit of using as therapeutic remedies.

Hemlock water and cowslip ointment is largely used to remove freckles and sunburn, while elder-flower ointment is held in high repute for healing cuts and sores, an infusion of nettles is believed to remove colds, and dandelion tea is regarded as a tonic of indisputable value.

Another much esteemed medicine is made as follows: Snails crawling up a church wall are caught—those crawling down possess no virtue—and are then placed in a pan with a little water, well boiled, being stirred the while with a quill plucked from a black crow. The result of this process will be a salve, which, if rubbed on the soles of the feet, will safeguard their owner against bodily ills, not excepting that fashionable complaint the "hinfooenzy." The ointment is said to be particularly efficacious in strengthening a weak spine.

Snails are looked upon as one of the most valuable remedies for consumption, and at least two specifics for rheumatism are known, one of which is a thread of scarlet silk, tied round the waist next the skin, and the other to keep a raw potato in one's pocket until it turns black, when it must be replaced by a fresh one. Rheumatism may also be transferred from a human being to a dog by compelling the latter to sleep on the patient's bed.

The tortures consequent upon an attack of cramps may be considerably mitigated by wrapping the feet together with a lump of sulphur in a large flannel bag. A village remedy for cancer is one consisting of "Turkey" figs boiled in new milk; the latter to be administered to the patient, while of the fruit a poultice is to be made.

The common fig wart can be recommended as an efficient emollient for boils and carbuncles, and the belief in the cure of king's evil—scrofula—by being touched by the hands of a royal personage, is still harbored in the breasts of many credulous countrymen.

The origin of various diseases is sometimes explained with more ingenuity than verisimilitude, says the writer in the *Spectator*. Thus diphtheria, it was explained, arises from an excessive consumption of green apples, producing in the stomach a disorder which thence mounts to the throat; imported food is likewise believed to account for much illness.

The terms applied to complaints of all kinds by village worthies are amusing. Consumption is generally known as "slime on the lungs," jaundice as "yellow janders," and such affections as "brantitis," "pamonium," "triatic," "insommania," and wandering bone are easily recognized by the rural solons of Eastern and Western England.

An old fogger remarked that he had been very middlin' lately, and that if he had not rubbed some "emigration" on his chest he did think he should have had the "purity in his side." His dame added that she had been obliged to put blisters on his head to keep his senses in.

The foregoing village diseases and remedies are but a few of the many that are known in those remote districts, and the wonder is that, notwithstanding the lamentable lack of knowledge of modern medical science displayed by the dwellers therein, they, as a rule, reach a ripe old age, far surpassing in this respect their more enlightened brethren of cities and of manufacturing localities.

Limburger as a Vehicle of Infection.

Dr. M. K. Allen, the Health Officer of Louisville, Ky., has aroused the ire of the German inhabitants of that city by placing a ban upon one of their favorite dishes, one, in fact, of national reputation.

The Louisville Health Officer asserts that the tasty cheese known as Limburger is full of microbes, and dangerous to health, and has issued an edict that anyone who makes or sells the article will be prosecuted to the full extent of the law.

Limburger, to persons of weak stomach and of sensitive olfactory organs, has long been an abomination, but to the robust son of Germany, whose digestive apparatus can assimilate many wonderful and weird foods, the Belgian cheese is a *bonne bouche* to be highly desired.

Undoubtedly, a ripe Limburger is in a state of putrefaction, and is not so wholesome an article of diet as a fresh cheese, but the Louisville Health Board Officer has probably exaggerated the dangers likely to arise from its consumption.

All microbes are not necessarily dangerous microbes. If such were the case, many viands now eagerly sought for would be the means of terminating the existence of numerous epicures.

In the eyes of the majority, or, rather, in the nostrils, the odor attached to aged Limburger is its most offensive quality, but if the natives of the Fatherland are willing to overlook this slight defect for the sake of its undeniably striking flavor, then those in this country of other nationalities will surely not object to sacrificing their feelings to this extent in the cause of their German compatriots.

Metabolism and Energy Within the Human Body.

Bulletin No. 109, U. S. Department of Agriculture, just issued, gives the results of experiments carried on by Atwater and Benedict of Wesleyan University, relative to the metabolism of matter and energy within the human body. In all, thirteen experiments were made with men by means of the respiration calorimeter, which was found to be a satisfactory instrument of precision. Thus, in the forty-five days of rest experiments, the average daily income of energy was 2,255 calories, and the outgo was determined by the calorimeter to be 2,250 calories, or a difference of but 0.2 per cent. In sixty-five days of work experiments, the income of energy amounted to 2,691 calories as a daily average, while the outgo, as determined by the calorimeter, amounted to 2,682 calories, or a difference of but 0.3 per cent. These differences are far within the limits of experimental error and physiological uncertainty, and show that the accuracy of the results attained with the respiration calorimeter cannot be successfully challenged in the case of continued experiment. For short experimental periods there is liability, of course, to considerable variation, due to the fact that it is impossible to assume that the quantities of material in the alimentary canal, and of carbohydrates in the body as a whole, are the same at the end as at the beginning of each day's experiment.

With respect to the food materials supplied and consumed, it was found that the diet supplied for rest experiments, about 2,425 calories, was slightly in excess—about 10 per cent.—of the actual needs of the body, while the amount of protein required under these circumstances was about 100 grams. In the work experiments, the work, consisting in riding a stationary bicycle for eight hours daily, the food required was such as would furnish about 3,750 calories, and about 100 grams of protein. The amount of protein required by the system, while performing the above amount of work, was unexpectedly small. As the investigators say, "The tentative standards for daily diet, which have been proposed by a number of investigators, have served a useful purpose, but they will doubtless have to be modified. . . . One principle, which, thus far, has not received adequate recognition in dietary standards, may be expressed by saying that the standard must vary not only with conditions of activity and environment, but also with the nutritive plane at which the body is to be maintained. A man may live and work and maintain bodily equilibrium on either a higher or lower nitrogen level or energy level."

The amount of water given off by the subjects from lungs and skin was found to depend largely upon muscular activity and the temperature of the surrounding air, and to be less affected by the income in food and drink. Thus, in one instance, the amount of water eliminated by the lungs and skin was two and one-third times as large in the work experiments as in the rest experiments.

The amount of carbon dioxide excreted was found to vary with the character of the diet and the time at which the last meal was taken, the muscular activity of the subject, the extreme temperature, the age and body weight, and individual differences.

The elimination of energy was found to be proportioned as follows:

	In rest Experiments Per cent	In work Experiments Per cent
From skin by radiation and conduction (and in exhaled air)	74.2	62.1
In urine and feces	1.4	[illegible]
In water vaporized from lungs and skin	24.4	[illegible]
Heat equivalent of muscular work done	:	8.4
Total	100.0	100.0

The energy given off per hour during work was more than twice as great as that given off during rest. Perhaps the most interesting results of the experiments were those which proved what had before been more than suspected, that the law of the conservation of energy applied to the human body.

THE DIAGNOSIS OF HYDROPHOBIA.

The diagnosis of rabies in its early stages is in every instance difficult if not almost impossible to accurately make. When a person is bitten by a dog who exhibits any symptoms of excitability or irritability, the suspicion is raised, and frequently the conclusion is immediately jumped to, that such an animal is suffering from rabies, and will inevitably inoculate those bitten by it with the infection.

Those who see the dog at the time are wont to exaggerate matters and to asserve that it was in a far worse condition than was, perhaps, really the case. Nevertheless, it is undoubtedly an error on the right side to quickly capture and kill a dog about whom there is a suspicion.

When, however, this has been done the dog's body should be reserved for the purpose of careful examination, because a post-mortem investigation is the only known means of deciding whether rabies is present or not. Even this method is not decisive, for no specific microbe of the disease has been as yet discovered, so that an examination of saliva, blood or tissues is of no avail. In those cases of the disease which have made much progress in the canine subject the medulla oblongata is found to be congested, and sometimes a portion of the nerves are more or less broken down.

With the object of throwing further light upon this matter, von Babes of Bucharest has been pursuing for a considerable time an exhaustive and interesting series of experiments. He managed to secure 487 dogs, presumably suffering from rabies. Portions of the medulla oblongata were injected into rabbits, and of these 410 died in from one to five weeks. Four-fifths of the cases yielded conclusive results by a microscopical examination of the brain tissue, while the remainder supplied no evidence of value.

The merit of this test lies in the fact that if it furnishes proof of the presence of hydrophobia it does so at once, whereas the inoculation method takes two or three weeks for the development of results.

Needless to say, it is of the most obvious importance to know as soon as possible whether a person has been bitten by a rabid dog or not, as this knowledge will decide the mode of treatment.

News of the Week.

Health Department of the City of New York, Willard Parker Hospital, Sixteenth Street and East River, Hospital Service.—A competitive examination for the selection of candidates for the position of interne to the Willard Parker and Riverside Hospitals will be held at the Willard Parker Hospital on Saturday, May 31, 1902, at 2.30 P.M. Each candidate is to serve one year from July 1, 1902, to July 1, 1903. The service consists of about four months as interne for the Willard Parker, four months as interne for the Riverside and four months as ambulance surgeon. Candidates must be graduates in medicine. Internes live at the hospitals during the term of service. No salary is attached to the position. The hospitals are devoted to the treatment of contagious diseases and their complications. Applications in writing should be sent to Dr. Henry W. Berg, 925 Madison avenue, New York City, Secretary of the Medical Board.

An Example Worthy of Imitation.—The proprietor of the *Gaceta Médica Catalana* recently received the sum of seventy-five pesetas from an anonymous subscriber who said he had defrauded the journal of that amount, being the price of over seven years' subscription. In making acknowledgement our pleased receiver begs that "as this conduct enobles rather than debases the sender may make himself known in order that he may be praised for the nobility of his act."

The International Medical Press Association met in conference at Monaco, on April 7, in order to decide whether a sufficiently common ground of agreement could be found to establish definitely an International Medical Press Association to draw up a scheme of statutes for such an association. A set of rules was adopted and it was decided that an International Congress of the Medical Press would be held a few days previous to the meeting of the International Medical Congress, which is to assemble at Madrid during the month of April next year. This plan of action is now endorsed by the delegates of the medical press associations of Austria, Bohemia, Belgium, Denmark, England, France, Germany, Holland, Italy, Norway, and Spain.

International Conference for the Prophylaxis of Syphilis and Venereal Diseases.—In a recent notice the date of this meeting was incorrectly given as September 15–20; it should have read, September 1–6. The discussions will be divided into the two main subjects of public and individual prophylaxis, each of these being treated of under several subheads. The Secretary-General, to whom all correspondence relative to the conference should be addressed, is Dr. Dubois-Havenith, Rue du Gouvernment-Provisoire, 10, Brussels.

A Woman Interne at the Gouverneur Hospital.—Dr. Emily Dunning, a young woman graduate of the Cornell University Medical School, has been appointed to the house staff of the Gouverneur Hospital. She passed the examination successfully some time ago, but was rejected by the former board on account of her sex. The present board decided that, as Dr. Dunning had passed the examination with high honors, and as quarters had been provided for women internes, there was no valid reason why she should not be given the appointment she had earned. The new interne will probably have to take the ambulance service, which is the rule for all internes, and as the Gouverneur Hospital district is the "toughest" in the city, it is not an enviable post. Pioneers, however, seldom have agreeable tasks, and Dr. Dunning's will prove no exception to the rule. The present internes are naturally, not especially pleased at the thought of a woman colleague, but, of course, will do nothing to make her task more difficult than it must of necessity be. New York is not the only city in which this experiment is to be tried, for we learn that two women are to be made internes at the Toronto General Hospital, and another is to be appointed to the staff of visiting physicians.

An Ambulance Launch for St. John's Guild.—An electric floating ambulance, the gift of Mr. J. Seligman to St. John's Guild, was launched at Bergen Point, N. J., last week. It is named the *Margaret*, after the donor's daughter. The launch is 38 feet over all, and is strongly constructed of oak and cedar. It will hold forty adults or sixty children, and has an opening in the roof to permit a stretcher to be passed through. It will go sixty miles on one charge and can attain a speed of ten miles an hour. It will be specially used to conduct the sick women and children from the hospital barges, which have to anchor a mile off New Dorp, Staten Island, where the guild has a seaside hospital, to the land hospital.

Professor Behring on Bovine Tuberculosis.—In a work on tuberculosis in cattle, just published in Berlin, Professor Behring asserts that the bacilli of human and bovine tuberculosis are identical, the seeming differences between them resulting from the capacity of the bacilli to accommodate themselves to the organism in which they live. The writer says he has successfully infected cattle with virus from human beings, producing thereby fatal animal tuberculosis. He also says he has rendered cattle immune against tuberculosis by vaccinating them when they are young. This he declares to be his greatest discovery, and says the method is in use on farms at Marburg. He alluded to this method of inoculating cattle in his speech at Stockholm some time ago, when he received one of the Nobel prizes.

The Late Dr. Walser.—The following resolutions were adopted by the Richmond County, N. Y., Medical Society at the April meeting: "Whereas, our associate and co-laborer, Dr. Theodore Walser, has been called by a divine Providence to a heavenly rest, at a ripe old age, and after a life well spent, Resolved, that we, his associates of the Richmond County Medical Society, of which he has been a prominent member for forty-seven (47) years, Vice-President four (4) years, and President two (2) years, in meeting assembled, hereby record our profound sorrow at the loss of so valued and esteemed a member of the medical fraternity, and our unanimous appreciation of his high professional worth, amiable character, and blameless life; *Resolved*, that the sympathy of this society be and is hereby extended to the family of the deceased in their sad bereavement; *Resolved*, that a copy of the above resolutions, suitably engrossed, be forwarded to the family of the deceased by the Secretary of the Society. William Bryan, M.D., Vice-President; Horace W. Patterson, M.D., Secretary.

Long Island College Hospital Alumni Association.—A scientific meeting of this society will be held at the Polhemus Memorial Clinic, Henry and Amity streets, Brooklyn Borough, on Saturday evening, May 10, at 8.30 o'clock. The medical paper, by Dr. Glentworth R. Butler, will be on "Difficulties in the Diagnosis of Certain Febrile Diseases," and will be discussed by Drs. Alfred Stengel and Francis Packard of Philadelphia, and W. H. Thomson and A. Jacobi of New York. The surgical paper, by Dr. John O. Polak, will be on "Early Diagnosis of Uterine Carcinoma; Surgical Limitations," and will be discussed by Drs. J. G. Clarke and J. M. Baldy of Philadelphia, and E. Janvrin and W. R. Pryor of New York. The profession in general is invited to this meeting.

The Florida State Medical Association.—The annual meeting of this society was held at Tampa in the second week in April, and was largely attended. The annual oration was delivered by Dr. Edward N. Liell, who took for his subject a review of recent studies in the etiology and pathogenesis of cancer. The following officers were elected for the ensuing year: *President*, Dr. J. Harris Pierpont of Pensacola; *First Vice-President*, Dr. Edward N. Liell of Jacksonville; *Second Vice-President*, Dr. J. McDiarmaid of De Land; *Secretary and Treasurer*, Dr. J. D. Fernandez of Jacksonville. The next place of meeting will be St. Augustine, the date of meeting being the second Wednesday in April, 1903.

The Winding-sheet of Christ.—The Paris correspondent of *The Lancet* writes that M. Vignon recently read a most interesting paper before the Academy of Sciences and exhibited some photographs which he had taken of the winding-sheet preserved at Turin and traditionally said to be that of Christ. This winding-sheet has on it certain markings printed in a brown color which, when photographed, gave a white imprint as does a negative when printed from. These markings, therefore, act as a true negative, and M. Vignon has shown by certain very careful experiments that cloth impregnated with oil and aloes, as was the winding-sheet in question, will receive an impression when in contact with ammoniacal vapors such as would be given off from a sweat very rich in urea, as is the case in the sweat of a person dying a lingering and painful death. Any idea of fraud need not be considered, for no one has touched this winding-sheet since 1353, and no painter at that date had the skill to reproduce such an exact drawing. The impression of the head is excellent. The wounds produced by the crown of thorns and the marks of the blood drops are quite obvious. The wound in the side and even the marks of the stripes produced on the back by the flagellation are also quite evident. Each of these stripes has at its end an enlargement such as would be produced by a cord with a ball of lead at the end. It is well known that this form of scourge was employed by the Roman soldiers and such a one has been found at Pompeii. Finally, the marks of the nails in the arms are not in the palm of the hand, but show that the nails were driven through at the level of the wrist. M. Vignon's paper has created an extreme interest, both in the scientific and the religious world.

Cholera in Manila.—Eleven men of the Eight United States Regular Infantry have died from the cholera. It is supposed that they contracted the disease while traveling from Manila to Laguna in cascoes. The total number of cases of cholera in Manila, up to May 2, was 703, and the deaths 554. The health authorities are placing additional protection around the water supply, and have placed school teachers in charge of the distribution of foodstuffs.

Retirement of Dr. A. Jacobi.—It is announced that after thirty-two years of active service as Professor of the Diseases of Children in the Medical Department of Columbia University, Dr. Abraham Jacobi of this city has severed his connection with that institution. The resignation will take effect in June, the end of the present term. Dr. Jacobi became a Lecturer on Infantile Pathology at the College of Physicians and Surgeons in 1857. In 1865 he was made Professor of Diseases of Children in the University of New York, but resigned five years later he was appointed to the same place in the College of Physicians and Surgeons.

The International Association of Railway Surgeons.—At the fifteenth annual meeting of this association, held last week in St Louis, the following officers were elected: *President*, Dr A W Candless of St Louis; *Vice-President*, Drs A I Wright of Iowa, John B Rule of St Louis, J C Wyser of Virginia, F. F Kitchener of Canada, W G Jamieson of Texas, and R Ortega of Mexico; *Secretary*, Dr Louis J. Mitchell of Chicago; *Treasurer*, Dr James A Duncan of Toledo, Ohio. Indianapolis was selected as the next meeting place.

No Quarantine Against Cuba.—This is the season when quarantine has usually been established at this port against Cuban ports, but Health Officer Doty has decided not to inaugurate the quarantine restrictions since Cuba is free from yellow fever and unusual care is being taken to keep it free. Indeed, Havana has much greater reason to quarantine against New York, because of smallpox, than the latter has to quarantine against Havana.

The Suffolk County, N. Y., Medical Society.—The annual meeting of this society was held at Riverhead, L. I., on Thursday, April 24 1902. Dr. George Ryerson Fowler read a paper on "Fracture of Lower End of Radius." The following officers were re-elected: *President*, John H. Benjaman, Riverhead; *Vice-President*, A. C. Loper, Greenport; *Secretary*, P. Van Benschoten Fowler, Centre Moriches; *Treasurer*, B. D Skinner, Greenport; *Librarian*, John H Benjaman, Riverhead.

Philadelphia Neurological Society.—At a stated meeting, held April 22, Dr. Wm. G. Spiller exhibited "A Case of Friederich's Ataxia." The patient was a young man, about twenty-one years old, in whom staggering gait and unsteady station had been observed since a year or two. In addition, speech was slow and indistinct, the knee-jerks were absent, the Babinski reflex was present, pupillary changes were lacking, nor was there girdle-sense or lancinating pains or other sensory disturbances. There had been no opportunity to examine the eyes thoroughly, but there was no evidence of gross impairment of vision. Dr. Alfred Gordon read a paper entitled "A Note on Some Psychoses of Early Puberty, with Report of a Case in a Boy Twelve Years Old." The patient was descended from neuropathic stock, and had periodic manifestations of delusions, hallucinations and impulses, and it was thought that the condition might pass over into that of dementia præcox. Dr. David Riesman reported "An Unusual Case of Myasthenia." The patient was a medical man who following an attack supposed to have been one of influenza, was overpowered by a sense of profound weakness, from which recovery took place in the course of two months. There was no involvment of sphincters, of sensibility, of reflexes, the electric reactions had not been studied. The nature of the disorder was not clear, and while for practical purposes a diagnosis of neurasthenia might suffice it was by no means satisfactory. In explanation of the phenomena it was suggested in analogy with the profound myasthenia of Addison's disease, that the condition here might be one of transitory functional inadequacy of the adrenal glands. Dr. Wm G Spiller reported "A Case of Tumor of the Pons Medulla Oblongata and Upper Part of the Spinal Cord with Necropsy." During life the symptoms pointed to the presence of a new growth in the neighborhood of the foramen magnum, and operation was advised against. Histologically the specimen presented appearances suggestive of a peritheliomа. Dr A R Moulton read a paper entitled "Attempted Self-castration." He reported the case of a man twenty-nine years old, suffering from depressive insanity with delusions of persecution, and who while dressed in a restraint suit by reason of an unsuccessful attempt at suicide managed with a safety pin to dissect one testicle out from the scrotum. As soon as the mutilation was discovered the organ was replaced and although the sutures sloughed the wound healed satisfactorily after a time. The mental state was in no way influenced by the experience. Dr. Chas W Burr read a paper entitled "Thrombosis of the Midcerebral Artery Causing Aphasia and Hemiplegia." The patient was a woman past sixty years of age, in whom the symptoms had developed some thirty years previously. There was absolute motor aphasia, but no word-deafness or word-blindness, although the post thrombotic softening resulted in destruction of the first temporal convolution and part of the supramarginal and angular gyri, in additon to the lower portion of the motor area. Dr. G A Pfahler made some remarks on "Cerebral Skiagraphy" and exhibited skiagrams of the normal skull and contents and of thrombotic softening. Dr W G Spiller exhibited a similar specimen for Dr. Chas K. Mills. Dr. J H W Rhein read a paper entitled "A Case of Ataxia with Recurrent Clonic Spasm in the Anterior Tibial Muscles." He referred to the various involuntary movements that sometimes occur in cases of tabes, and to which little attention appears to have been given by English and American observers. Dr. F. R. Savary Pearce exhibited a specimen of "Hydrocephalus" obtained from a colored child presenting typical clinical manifestations. No underlying cause for the conditions was discovered.

Pathological Society of Philadelphia.—At the annual conversational meeting, held April 24, Dr. Mazyck P Ravenel delivered an address entitled "The Intercommunicability of Human and Bovine Tuberculosis." While admitting certain differences between human and bovine tuberculosis and between the bacilli found in association with both, particularly the greater virulence of the bovine tubercle bacillus, convincing evidence was adduced to show that the disease is transmissible between human beings and cattle. Dr. D. E. Salmon of the Bureau of Animal Industry of the Department of Agriculture said that while it must now be admitted that there is danger in the consumption of milk and flesh of tuberculosis animals, it is difficult to determine the exact degree of such danger. Dr Leonard Pearson of the Pennsylvania State Live Stock Sanitary Board pointed out the inadequacy of the existing provisions for detecting and preventing the sale of tuberculous milk and meat. A good deal in the way of suppressing tuberculosis in cattle has, however, been done, and by this means the risks to the community have been lessened. The farmer and dairyman has been encouraged to segregate and to destroy the tuberculous animals in his herds, and so far as possible the State has come to his aid.

College of Physicians of Philadelphia, Section on General Medicine.—At a stated meeting, held April 14, Dr. J. J. Abel of Baltimore read a paper entitled "The Chemistry and Physiology of the Adrenals." He pointed out that his own investigations, conducted over a period of several years, go to show that the active principle in the adrenal bodies is an alkaloidal substance known as epinephrin, the various other substances obtained from the same source being modifications thereof. Dr. Simon Flexner presented a communication entitled "The Pathology of the Adrenals," reciting the several morbid conditions of which the adrenal bodies may be the seat and devoting especial attention to the question of the symptom-complex known as Addison's disease. Dr. Wm. Osler of Baltimore read a paper on "The Clinical Manifestations of the Diseases of the Adrenals." He dwelt at some length upon the symptomatology of Addison's disease and cited a group of cases that had been under his own observation, and in some of which encouraging results had been obtained from the administration of preparations of the adrenal glands. Dr. Alfred Stengel presented a communication entitled "Therapeutic Uses of the Derivatives of the Adrenals," in which he reported the employment of these substances in cases of glycosuria (resulting in increase of the amount of sugar in the urine), in cases of typhoid fever and of exophthalmic goiter—to increase arterial tension, in cases of hemorrhage—as from gastric ulcer. Dr. G. E. de Schweinitz read a paper on "The Use of the Adrenal Preparations in Diseases of the Eye." He pointed out the great value of these agents in removing hyperæmia and controlling hemorrhage, but there is little evidence of any definite curative effect in the presence of any special disorder. Dr. D. Braden Kyle read a paper on "The Use of the Adrenal Preparations in Diseases of the Nose and Throat." He also had found that in some cases these preparations had certain useful symptomatic applications, without any obvious curative value. The results, however, have been variable and the reports recorded in the literature have been most diverse in character.

A new training school for female hospital nurses, erected almost entirely by American contributions and operated by medical missionaries, was recently opened at Canton, China. This is the only institution of its kind in South China.

Dr. A. S. Ambler, Superintendent of the Brooklyn Hospital, has resigned his position as head of that institution.

Northern Medical Association.—At a stated meeting, held April 25, Dr. A. A. Eshner read a paper on "Sciatica." He defined this condition as the result of an irritation of the sciatic nerve, at times proceeding to inflammation, at other times falling short of this. The exciting factors may be physical or chemical. Among the former are traumatism and extremes of temperature; among the latter are poisons introduced from without or generated within the body as a result of metabolic disturbances or infectious diseases. Causes of local operation determine the localization. The essential symptom of sciatica is pain, usually paroxysmal and radiating and referred especially to certain points; in the presence of neuritis the trunk of the nerve may be tender. The treatment comprises rest, elimination, sedation, counterirritation. Dr. D. J. McCarthy presented a communication entitled "Symptomatology, Pathology and Treatment of Migraine." He related the case of a woman, in some members of whose family there was a history of migraine, while others exhibited disorders of the blood and vascular system. In connection with the attacks of headache there was transitory graying of the hair. At a later period the sensory storm was replaced by epileptiform attacks of focal character. The condition was believed to be due to vasomotor disturbances affecting the cortex of one or the other cerebral hemisphere. Dr. P. N. K. Schwenk read a paper entitled "Headache from Eyestrain and Other Ocular Affections." He described the refractive and muscular mechanism of the eye, as well as the conditions that give rise to strain and the consequent manifestations.

The Mayor of San Francisco Condemned by the California State Medical Society.—At the annual meeting of the California State Medical Society, held April 15–17, the following resolution was adopted: "Whereas, The Mayor of the city of San Francisco has seen fit to remove the so-called old Board of Health; and Whereas, The Chief Executive of the city has stated that he has determined, after a prolonged personal investigation, that bubonic plague has never existed in San Francisco; and Whereas, The position is absolutely unsupported by any competent, unprejudiced physician who has made personal examination of suspects or alleged cases of plague before or after death, or who has examined the bacteriological evidence presented, and is further in direct conflict with the findings of the Federal Government experts and Special Commission; therefore be it *Resolved*, That the Medical Society of the State of California emphatically condemns this action on the part of the Mayor of San Francisco, and at the same time endorses the position always maintained by the old Board of Health in its sanitary defence of the people of the city of San Francisco and of the country at large.

Reciprocity in Medical Licensure.—At a meeting of representatives of the medical examining boards of Illinois, Wisconsin, Indiana, and Michigan, held in Chicago in January, a committee was appointed to formulate a policy for reciprocity in licensure between the several United States. The report of this committee, which was adopted at the meeting, submitted the following propositions: (1) That a license or certificate of qualification of at least one year's date and based upon presentation of a satisfactory diploma, and an examination before a board in specified branches of medicine and surgery, may be accepted at the discretion of a board in lieu of an examination, and as a basis upon which the license of a State may be issued; (2) That a license or certificate of qualification issued by a State Board of Registration or Medical Examiners of at least one year's date, based upon presentation of a satisfactory diploma and upon the recommendation of a State Board of Registration or Medical Examiners as to the reputability of the applicant, may be accepted at the discretion of a board in lieu of an examination, and as a basis upon which the license of a State may be issued. Owing to the differences which exist in medical laws in the different States it was only possible for the confederation to recommend the policy upon which the reciprocal exchange of certificates could be accomplished. The details of such reciprocal exchange of certificates must be arranged between States reciprocating; also, the standard of preliminary education, as well as that of the medical qualifications of licentiates, must be a matter of agreement between reciprocating States. The secretary of the "Confederation of Members of Reciprocating State Medical Examining and Licensing Boards," is Dr. B. D. Harrison, Sault Ste. Marie, Mich.

Examination of a Physician for the Indian Service.—The United States Civil Service Commission announces that on June 3, 1902, an examination will be held at the usual places for the position of physician in the Indian Service. From the eligibles from this examination it is expected that certification will be made to the position of physician at the White Earth Agency, Minnesota, at a salary of $900 per annum, and to fill similar vacancies as they may occur.

This examination is open to all citizens of the United States, between the ages of twenty-five and sixty-five years, who comply with the requirements. Persons who desire to compete should at once apply either to the United States Civil Service Commission, Washington, D. C., for a copy of the Manual of Examinations and Application Forms 304 and 375. The Applications should be properly executed and filed with the Commission at Washington prior to the hour of closing business on May 23.

Obituary Notes. Dr. Joseph P. Turner died at Trenton, N. J., on April 27, at the age of seventy-nine years. During the Civil War he was surgeon to the First New Jersey Cavalry.

Dr. [illegible] died at Greensburg at the age of eighty-seven years. He was a graduate of Jefferson Medical College, and he represented his county in the legislature in 1861 and 1862.

Dr. Cyrus T. Hertenstein died in Philadelphia on May 1, at the age of seventy-three years. He was graduated from Jefferson Medical College in 1848 and for twelve years was engaged in the practice of his profession at Portage, Wis. In 1860 he removed to Columbia, Pa., becoming surgeon for the Philadelphia Division of the Pennsylvania Railroad. Shortly after the outbreak of the Civil War he went to the front with the One Hundred and Thirty-fifth Regiment, Pennsylvania Volunteers. He became Surgeon-General of the Third Division, First Army Corps, to which his regiment was attached, and as such remained on the staff of the Division Commander, General Doubleday, until he was mustered out. He was present at the second battle of Bull Run and also at South Mountain, Antietam, Fredericksburg, and Chancellorsville. On his return to civil life he resumed his relations with the Pennsylvania Railroad, and these were continued until 1897. He was for more than twenty years physician to the Working Home for the Blind.

Dr. Philip F. Fulmer, of Dingman's Ferry, Pa., died suddenly while attending the funeral of a friend at Port Jervis, N. Y., on April 29. He was born in Stewartsville, N. J., in 1830, and was graduated from the Medical Department of the University of Pennsylvania in 1853.

Dr. Charles H. Masten, of Nyack, N. Y., died of pneumonia on May 1, at the age of sixty-three years. He was born in Odelltown, Province of Quebec, Canada, August 21, 1839, and came to New York when about thirty years old. He studied medicine in Bellevue Hospital Medical College, and after graduation, in 1867, settled in Rockland county, where he has since lived and practiced medicine.

Dr. Joseph Asbury Tarkington died at Greensburg, Ind., on May 1. He was a graduate of the Medical Department of the University of Georgetown, D. C., in the class of 1870, and until recently practised in Washington.

Dr. D'Estaing Dickerson, of Kansas City, Mo., died at his home in that city on May 3, at the age of sixty-seven years. He was born in Watertown, N. Y., and was a graduate of the Albany Medical College in the class of 1857. During the Civil War he was in charge of all the hospitals of the Sixth United States Army Corps.

Dr. Benjamin Lord, formerly a prominent dental practitioner of this city, died on May 3, at the age of eighty-three years. He was born in Trenton, N. J., and began the practice of dentistry in New York sixty years ago. He was an active worker in many scientific societies and a frequent contributor to dental journals during the period of his professional life.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PARLIAMENTARY—THE NAVAL REGULATIONS—CYSTS OF THE NECK—INTESTINAL OBSTRUCTION FROM EMBOLISM—[illegible] ABSCESS—[illegible]—[illegible] THE NAVAL [illegible]—[illegible]—OBITUARY.

London, April [illegible], 1902.

In reply to a question in the House of Commons on Monday, Lord Stanley said the report on anti-typhoid inoculation had been received, and it dealt with only 4,138 cases; in these the aggregate results show a mortality of 8.2 per cent. in inoculated persons, against 15.1 per cent. in uninoculated persons. It was considered advisable to obtain further statistics from the admission and discharge books before publishing the report.

The select committee to inquire into the ventilation of the House was nominated on Tuesday. Members were sufficiently alive to their own interests to include Sir M. Foster, Sir J. B. Tuke, and Dr. Farquharson.

The Cremation Bill was read a second time and referred to the Grand Committee on Law. This bill has already passed the upper house.

The passing of the kilt is threatened. Highland regiments are discontented, and various questions have been put, but the War Secretary has said the kilt is not to be abolished. He had to admit that he could not say whether the kilted men suffered less from stomach diseases in consequence of wearing the national dress. It is rumored that the authorities were concerned for the soldiers' knees.

The new regulations for the naval medical service are in no wise revolutionary. Power is reserved to admit a couple of candidates, who have been house surgeons, on the nomination of the medical schools, and six others recommended by the Colonial Universities. There is also an advance in pay, but not in retired pay and allowances. The entrance examination has been revised. The most important point in the new regulations is that every medical officer will have to take a post-graduate course at a metropolitan hospital every eight years if the exigencies of the service permit.

Last Friday, at the Clinical Society, Mr. Carwardine, of Bristol, read a paper on the mode of origin of cysts in the neck. He said cysts and fistulæ arising from the thyroglossal duct usually had a pedicle which passed through the thyrohyoid membrane in the middle line below the hyoid bone, between the body and the thyroid cartilage. These he proposed to name thyrohyoid cysts. He had met with a case in which the pedicle passed through an interval in the cervical fascia into the middle of the cricothyroid membrane, after which it might vary well be named a cricothyroid cyst. Another case in a similar way he called hyomandibular. Thus there were three median cysts named as above. Lateral cysts were also distinguished and their origin given.

Dr. Tyson then related a case of intestinal obstruction, due to embolus of a branch of the superior mesenteric artery. The patient was a woman of sixty-six, and the symptoms those of colic which gradually passed to coffee-ground vomiting. On laparotomy the small intestine was adherent in the right fossa, where about a foot of gangrenous bowel was found. Excision was done and Murphy's button used, but she died thirty-six hours afterward. At the post-mortem examination atheromatous erosion of the descending aorta was found, with blocking of a branch of the superior mesenteric artery.

Mr. Lunn described a similar case, and Mr. Marsh mentioned that of a man thrown from his horse and falling on his abdomen on a heap of stones. No grave symptoms occurred for a few days, after which acute obstruction led to operation. This revealed gangrenous bowel, and post-mortem embolism of the superior mesenteric artery was found. Mr. Bowlby mentioned a case of gangrene of the fingers from frost bite, after which abdominal symptoms came on and were fatal. On post-mortem a general condition of embolism of the mesenteric area was discovered.

Mr. Barker described a case diagnosed as intracranial abscess with thrombosis of the lateral sinus and jugular vein, in a girl of fourteen. On lifting her to take her to the operating theatre respiration suddenly ceased. The heart continued to beat, but no sign of normal breathing, in spite of artificial respiration and oxygen inhalation, kept up for an hour. Then he operated and reached foul gas and pus, and kept up the artificial respiration, etc., but without success. The heart continued to beat for two hours and thirty-five minutes from the time natural respiration ceased. At the post-mortem examination a cerebellar abscess was found, which had been partially exsected by the operation.

Mr. Barnard then introduced the subject of simulation of acute peritonitis by pleuropneumonic diseases, observing that Andral recorded several typical cases quoted by Watson, and Fagge added one. But modern writers give only vague indications of the diagnosis, which Mr. Barnard considered easy, if the suspicion is once aroused. Sir D. Duckworth said if such cases were properly examined on admission, mistakes would not occur—a remark which, with more or less force, may be made of most cases for which differential diagnosis is laid down in the textbooks.

A paper by Mr. Mayo Robson on the surgical treatment of obstruction in the common bile duct by concretions, with special reference to the operation of choledochotomy, as modified by Mr. Robson, and illustrated by sixty cases, was read on his behalf at the Medical and Chirurgical Society, on the 25th ult. Regret was expressed at the absence of Mr. Robson, and a desire to ask him some questions of detail. The paper said gallstones could not be removed by medical means when once they had reached the common duct, unless very exceptionally. In an experience of numerous cases Mr. Robson found the common duct had to be dealt with in one out of every five or six cases. In ten he had been able to manipulate the stones back into the gall-bladder, and then remove them; in more than thirty he had crushed the stone in the duct—a plan only to be attempted for soft stones, and where the fragments could be removed. Short circuiting the obstruction left the cause untouched, and was, therefore, inadvisable. Uniting the gall-bladder to the colon was as efficient as uniting it to the duodenum, and simpler. Opening the common duct through the opened duodenum was not necessary, and introduced danger of sepsis. Choledochotomy was the only operation to be trusted, and could, by his improved method, be performed in thirty to forty minutes. The mortality before 1900 was 23.8 per cent. Since January 1, 1900, it had only been 7.4 per cent. and he thought it might yet be reduced to 5 per cent. or less. In the last series of twenty-one consecutive cases operated on since July of last year, he had no death; and, in all his cases since June, 1900, the mortality has only been 5.5 per cent.

Sir D. Duckworth said medical measures could not remove gallstones, but might prevent their formation. Operation should not be delayed too long. Rise of temperature was a good indication.

Mr. Godlee emphasized the septic nature of the contents of the duct and the care necessary to prevent its escape. The influence of the bile in digestion would be lost by uniting the bladder to the colon instead of the duodenum.

Dr. Keay thought medical means might do some good, and referred to oil. He would like to know the subsequent history of the cases as recurrence was not uncommon. The president (Mr. Willett) would have liked to ask how often on operation no stone was found, as he had met with cases in which all the symptoms were present, but no gallstone.

Dr. E. E. Glynn has communicated to the Liverpool Medical Institution the results of his bacterial examination of the water of the public swimming baths of that town. When fresh in the morning the water was practically sterile, not more than three bacteria per c.cm. being present. An hour after the baths were opened the number had risen to forty-six. At 9 P.M., on five occasions in June and July, there was an average of 4,676 bacteria per c.cm. in water of the first-class baths; the average number of bathers being 292. In the second class the samples of three occasions gave 11,970 per c.cm. bacteria; the number of bathers averaging 186. Basing his calculation on the capacity of the baths, Dr. Glynn reckons that the water removed from the skin and hair of each bather between four and six thousand million bacteria. But some of the pollution arose from the corridor between the edge and the dressing baths, where both bathers and those waiting walked about, rendering it muddy soon after the opening. To prevent this, Dr. Glynn says, the baths should have a second corridor outside the boxes. Streptococci were never found; staphyloccus aureus and citreous only very rarely; but S. albus was abundant in three varieties, pyogenes albus, cereus albus, and epidermidis albus. B. coli was present at the end of the day to the number of eight per liter for each bather in the first class, and forty-eight in the second. Dr. Glynn said typhoid was probably never contracted in such baths, and swallowing the water was innocuous. He considers Liverpool fortunate in the number of its baths and the quality of its water.

Lieut. E. Blake Knox, Royal Academy Medical Corps, has published, under the title of "Buller's Campaign," an account of the fighting in Natal, throughout which he served. To those who complain of slow progress in that campaign, Lieut. Knox says, "Go and see the country, and weigh all the circumstances; and it is highly probable your opinion will change."

The "Medical Register for 1902" was issued last week. April seems late for the appearance of such a work. There are 36,912 practitioners registered.

New associations are continually being formed. A "medico-legal society" was established, and its first officers elected on the 5th inst. A "Betterment of London Association" has also been formed, which promises to make the metropolis a more healthy and attractive residence. I wish it success in its arduous enterprise.

Dr. Alexander Macgregor died suddenly on the 12th inst., aged forty-eight years. He came to London six or seven years ago from Aberdeen, where he had a large practice, and was an assistant professor.

Another death, which would be termed sudden in a younger member of the profession, is that of Mr. R. H. Chilton, Registrar of the Bristol Children's Hospital, where he contracted diphtheria. He had passed through the acute stage and seemed likely to recover, when cardiac failure supervened. He took his qualifications in 1893, and his promising career closes in his thirty-first year.

IS THE MIND AN ENTITY?

To the Editor of the Medical Record:

Sir: With extreme brevity I wish to suggest a few points which demand recognition in a discussion of this subject and which the materialistic standpoint fails to satisfy. This résumé is called out by an article of the same name by Dr. H. H. Stoner in the Medical Record, March 29, 1902, which he offers as a counterpart to my article on "The Psychic Half" in the Medical Record, December 7, 1901:

(1) The necessity for unity, in order to have thought, is imperative. Unity is not demanded by psychology alone, but it is a *sine qua non* of all sciences.

(2) There is no real unit in the so-called physical sciences. Hence their resort to hypothetical units. The cell is anything but a unit and the atom is but a hypothetical unit based by analogy on the unity of consciousness.

(3) Sensation is not an elementary something that can be separated from a precede consciousness. "Unconscious sensation" is a contradiction. The simple sensation is to psychology what the atom is to physics—viz., an abstract hypothetical unit by which to explain experience. Neither simple sensation nor the atom exists as an object of experience.

(4) Self-consciousness finds no place in a nervous mechanism, as such.

(5) Space has no objective reality; location and size do not apply to consciousness.

(6) Ideals refer to a unit as their subject.

(7) "Ought" and the moral obligations relative thereto are demanded under any "ism," inadvertently though it may be.

(8) Causation is but a physical law, *deduced* from the self-consistent activity of reality. The ultimate principle of existence is spontaneity of activity. All attempts to correlate force as an active principle with matter as a mere subject of such activity lead to interminable inconsistency and contradiction.

(9) Independent existence is an abstraction having no counterpart in experience. To be an entity does not mean independent existence. "To be is to be related" and relation is found in consciousness alone.

(10) Existence and knowledge are axiomatic. All so-called explanation assumes and accepts the unexplained.

J. Allen Gilbert, Ph.D., M.D.

Portland, Oregon.

Observations on the Early Diagnosis of Typhoid Fever.—R. Polacco and E. Gernelli seek to lighten the task of the clinician in the diagnosis of typhoid by calling attention to the feasibility of obtaining the specific organism from the rose spots without the difficult technique required to isolate it from the stools and before the Widal reaction is positive. Neufeld's method was employed and gave positive results in fifty successive cases. Essentials for success are the use of fluid media, since the bacilli are usually so few in number that cultures on solid media are negative, and that the cultures be taken from at least two of the spots. The authors believe that the organism is always to be found in this way, and that the method affords a convenient and rapid means of diagnosis.—*Centralblatt für innere Medicin.*

Progress of Medical Science.

Journal of the American Medical Association, May 3, 1902.

Blackwater Hæmoglobinuric Fever.—J. J. Curry reports two cases of this disease occurring in the United States Military Hospital at Manila. The name is applied to a disease generally spoken of as non-contagious, which is characterized by the presence of hæmoglobin in the urine and by a marked jaundice. There is a difference of opinion as to its causation, some ascribing it to malaria, while others place it in a different category. During a hæmoglobinuric paroxysm quinine appears to be distinctly harmful. But this remedy may be given with advantage in the intervals between the attacks, and should also be given in cases in which active malarial parasites are present in the blood during an attack and in which the hæmoglobinuria comes on after a succession of malarial attacks.

The Functions of the Soluble Ferments of the Blood in Intracellular Digestion.—According to A. C. Croftan, assimilation and dissimilation of food occur in two stages. (1) An anaërobic stage in a reducing medium in the absence of oxygen, in the interior of the cell. (2) An aërobic stage in the presence of free oxygen (hæmoglobin) at the periphery of the cell, i.e., chiefly in the blood and lymph stream. Both processes, it appears, are inaugurated by the intervention of soluble, chemical, unorganized ferments that the cells secrete. The term "intracellular" digestion is essentially synonymous with general metabolism. The fermentative changes in the gastroenteric canal are essentially hydrolyses, by which diffusion through the membranes is facilitated. In the passage of the hydrolyzed products through the bowel wall they are reconverted, and these processes have been shown to be due to enzyme action. The question arises, where do these processes occur? In the mucosa, the muscularis, the serosa, the lymph or blood stream? Presumptive evidence is overwhelming in favor of the supposition that the leucocytes in the blood and lymph capillaries of the intestinal wall are in some way concerned in this process (digestion leucocytosis). All the ferments are so toxic when circulating freely, and are still so universally present that we can only assume that mobile cells, like the leucocytes, bear them in a harmless form through the blood and lymph-stream to their ultimate destination, while we have so far been unable to demonstrate experimentally that the cells of our body, like certain bacteria, secrete enzymes that bring about the processes of proteolytic anaërobic fermentation, we are able to show experimentally that the second, oxidative stage of dissimilation of fats, carbohydrates, etc., is due to the action of numerous soluble ferments that are present in the blood and lymph. Whether the blood ferments, after they perform their function, are destroyed, eliminated, re-inclosed in leucocytes, arrested in the digestive glands to be re-excreted, or finally are held by such dis-intoxicating organs as the suprarenals, the thyroid and the liver it is impossible to say. As the urine nearly always contains some of the ferments, as they are nearly always present in the liver, and as they certainly must suffer the ultimate fate of all the other constituents of the body, it is probable that all these processes can and do occur.

New York Medical Journal, May 3, 1902.

A New Treatment for Deafness from Chronic Catarrh of the Middle Ear; a Preliminary Report.—W. H. Bates finds that in some instances of the nature described in the title of his paper hearing is improved by the removal of the excess of connective tissue from the inner wall of the tympanum. To obtain room for the treatment of the region of the oval window he found it necessary to remove not only the membrana tympani and ossicles, but also the upper and outer bony wall of the external auditory canal with the outer wall of the attic and aditus and antrum. For the removal of the connective tissue he has found the most serviceable instruments to be a Graefe cataract knife, a Sexton [illegible] knife, and Wilde's forceps. The operation has been done under cocaine in combination with the use of adrenalin. The immediate effect of the removal of the connective tissue was a temporary loss of hearing, due, the author believes, to the reaction from the use of the knife. He further states that two days after a mass of connective tissue is removed the open space will be replaced in part by a soft material, which becomes in a week hard and fibrous. He believes it best to remove the soft material as rapidly as it forms and also as much of the firmer tissue beneath it as can be done without much reaction or a lowering of the hearing. If one waits the tissue becomes very dense, and more difficult to remove for this reason, and, what is more disadvantageous, it is more sensitive to pain, and the reaction increase of new tissue is greater.

Medical News, May 3, 1902.

The Right and Wrong Use of Digitalis Based on Cardiac Pathology.—William Henry Porter reviews the various effects of digitalis. It increases primarily the motor force of the heart muscle. It increases at the same time the resistance offered in front of it so that the rapidity of action of the heart must be diminished in order to increase its working capacity. In both insufficiency and stenosis of the left auriculoventricular orifice digitalis improves the condition temporarily. It also increases the systolic contraction and more completely empties the contents of the ventricular cavity into the aorta. In both lesions of the mitral valve the pulmonary congestion is overcome, and the dyspnœa consequent upon the pulmonary engorgement is removed. Once the normal tension has been reached and passed, the action of the digitalis is detrimental to all the physiological functions of the body. In aortic lesions, either of incompetency or stenosis, digitalis is not indicated at any stage. In fatty degeneration or any enfeebled condition of the heart muscle digitalis is contraindicated. In hypertrophy of the heart digitalis is a dangerous remedy. The drug is of service only for a few days at a time at the longest. It should only be given to influence the heart and circulation when the arteries are very much relaxed, and the pulmonary or systemic veins overfilled with blood.

Intravenous Infusion of Saline Solution.—George Crile declares that normal saline solution is efficacious in shock in proportion to the impairment of the vasomotor mechanism. If this mechanism has gone into resolution, infusion is without curative effect. If the impairment is considerable, the infusion will partly restore the pressure. The peripheral resistance determined the height of the blood-pressure, no matter how swift the stream, nor how great the volume of blood. If the peripheral resistance is lost (fatal "shock"), no amount of infusion can more than temporarily and partly restore the blood-pressure and death is inevitable. If the shock is much increased by so-called vascular hemorrhage, as in operations on the splanchnic area, infusion may be effective because peripheral resistance is still present. If hemorrhage complicates shock and the vasomotor mechanism is still intact, infusion is effectual. As to the effect of the varying height of the saline column, it has been noted that increasing the height of the bottle but slightly increased the blood-pressure. As to drug effects, after a considerable amount of saline solution had been infused, the inhalation of chloroform even in small dosage produced marked depression of the circulation. Strychnine and nitroglycerin produced their usual physiological action, though to a lesser degree. Thermal, electrical, and mechanical stimulation produced the usual effects. In cases of dangerous hemorrhage the combination of oxygen inhalation with saline infusion is beneficial.

Philadelphia Medical Journal, May 3, 1902.

The Surgery of the Heart.—H. L. Nietert believes, from his experience in the suturing of heart wounds, that (1) Gentle manipulation may be applied without producing shock. (2) The introduction of the suture produces but a slight irregularity in the heart's action. (3) Heart wounds heal rapidly. (4) Intrapericardial pressure is increased even if hemorrhage occurs during diastole alone. He insists that all heart wounds, in which there is danger of fatal hemorrhage, should be sutured. If the wound does not involve the pleura, the extrapleural route should be employed, but if the pleura has been injured, the intrapleural method should always be employed, and the flap devised by Rotter is the best. Although it is advisable for the surgeon to familiarize himself with the methods of operation and the flaps devised by the different operators, a thorough knowledge of the anatomy of the region is most essential and each operator should modify the flaps as best suits his case. The writer reports a case in detail. The patient was a man of twenty-seven years, who was stabbed in the heart. The wound was sutured and the patient has almost completely recovered, there being noticed only a slight dyspnœa on violent exertion, which is probably due to the weakened condition of the heart.

The Relation of Uric Acid and Xanthin Bases to Gout and the So-called Uric Acid Diathesis.—David L. Edsall in his discussion of this subject thinks that the main question to be decided is whether uric acid causes both general toxic symptoms and local toxic symptoms as well as the symptoms of irritation that would be caused by any foreign body, whether it causes some or all of the local toxic and mechanical symptoms but no general symptoms of importance, or whether it causes no symptoms at all that can be directly attributed to it, excepting those which would be produced by any foreign body deposited about the joints. He believes that it is probable that uric acid does not cause any notable evidences of intoxication and does not produce the decided general symptoms of the disease. However, uric acid may produce much of the local difficulty in gout at the time of the attack, as well as in the interval, through its local toxic action when present in extremely concentrated form. There is only weak ground for the belief that it has a purely mechanical action in gout. The writer thinks that the rôle of uric acid in gout may be compared with that of sugar in diabetes, the intoxication being referred in general to some other toxic substance or substances as yet unknown. He suggests, as a remote possibility, that the uric acid in the blood in gout is, in part at least, present in a form which is toxic while it is not notably toxic in other conditions. This is extremely improbable. As to the xanthin bases, there is not an increase of these excreted in gout, and so far there is no reason for thinking that disease of the kidney has any influence upon the oxidation of xanthin bases to uric acid. That some of the xanthin bases are toxic, proves nothing concerning gout or the uric acid diathesis. Besides the xanthin bases there are numerous excretory substances that are toxic, but we do not think of them as the cause of gout or the uric-acid diathesis. There is no better reason for thinking that the xanthin bases are the actual cause of these conditions. The writer concludes by saying that the use of bad methods has led to a great waste of time in the study of the xanthin bases.

American Medicine, May 3, 1902.

On the Effect of the Digestion of Gelatin on Its Styptic Properties.—Horatio C. Wood, Jr., concludes that: (1) Pepsin digestion of gelatin does not destroy its coagulating effect on the blood; (2) The resulting product is dialyzable, and, therefore, capable of absorption; (3) The administration of gelatin by the mouth in the treatment of hemorrhage is, therefore, a rational procedure; (4) Gelatose seems to antagonize, if given in sufficient quantity, the anticoagulating action of peptone.

Indications for the Mastoid Operation.—Lee Wallace Dean states that mastoiditis is usually caused by an involvement of the membrane lining of the opening which connects the antrum of the mastoid with the middle ear. The swelling of the membrane occludes the opening, from which there results stagnation of the secretion in the cavities of the mastoid. If pyogenic microorganisms develop in this secretion, mastoiditis takes place. Although in most cases of mastoiditis the characteristic symptoms are marked enough to make diagnosis comparatively easy, there are cases, especially those of tuberculous origin, in which all these symptoms may be absent, and yet there may be very extensive necrosis of the mastoid cells. This destruction may take place without any pain. When mastoiditis develops, it is best, in the beginning, to give laxatives and apply, by means of Leiter's tubes, cold over the region of the mastoid. If there is decrease in the intensity of the disease within two or three days, the treatment should be kept up. If, however, the disease becomes worse, or even remains at a standstill, or if symptoms of meningeal disturbance develop, operation should be performed without delay. The danger in mastoiditis lies not in the operation, but in not operating. There is little danger if the operation is performed under perfectly aseptic conditions; the patient will suffer little discomfort besides that which results from the anæsthesia. The patient may die as the result of the previous condition, but very few die as the result of the operation.

The Lancet, April 26, 1902.

On Some Points in the Treatment of Puerperal Eclampsia.—G. E. Herman asks what the effect is of emptying the uterus in eclampsia; whether it stops the convulsions and what good it does do. From the collation of quite a large lot of figures, embracing over 2,000 cases, he shows that the mortality in cases in which emptying of the uterus is left to the natural powers is only 1 or 2 per cent. greater than in the cases of rapid delivery induced by approved methods. The second question relates to the good effect of the tepid bath when used to reduce temperature in certain cases of eclampsia. This procedure he most heartily commends in those cases characterized by an especially high fever. One case is given in detail. In this case there were stupor and some muscular twitchings, but no actual convulsion.

Note on a Case of Nearly Fatal Intralaryngeal Hemorrhage from Papilloma of the Larynx.—A. Bronner reports the case of a man forty-eight years old with papillomata of the false and true cords. These were removed at intervals without any special incidents. On one occasion while running to catch a train he began to raise considerable blood and feel as if he was going to suffocate. The hemorrhage continued and the man became insensible, but was brought around and in two days was in his usual condition. He was seen quite awhile after by Bronner, who could distinguish in the larynx a small clot in a papilloma, and removal of the clot was followed by a small loss of blood. There was nothing in the patient's condition to suggest lung or other visceral trouble, and these facts, together with the fact that the original bleeding came on after violent exertion, led Bronner to conclude that the papillomata were the source and site of the hemorrhage.

A Case of Relapsing Pyrexia Continuing for Fourteen Months Unabated.—S. H. M. Neave reports the case of a boy of seventeen years, who, without apparent cause, began to have regular attacks of pyrexia with an intense desire to sleep. In the course of six months he passed through nine cycles of pyrexia and remissions of fever in 172 days, making an average of nineteen days each. During these attacks the patient had very little discomfort. He was drowsy, had some bronchitis, the tongue was furred, and at the highest point of the temperature he usually vomited. There was some tenderness over the spleen, and the blood count showed a leucocytosis. The blood was examined by various pathologists for malarial organisms, for the reaction of Malta fever and for the spirillum of Obermeier, but all without any definite findings. In the intervals between the attacks he appeared fairly well, though he was anæmic—the blood showing a deficiency of hæmoglobin—without much wasting, and he felt quite well. After six months, however, he began to lose weight. Every chance of a collection of pus was well considered and investigated; *imprimis*, cholecystitis with hepatic intermittent fever was kept well in view, and there was never any sign of jaundice. The cerebrospinal fluid was sterile. There were no renal symptoms and the urine was normal. A negative result likewise followed the exploration of the nose, the nasopharynx, the larynx, and the rectum. There was no affection of the special senses, and the fundus oculi and the ear were normal.

The Spontaneous Cure of Senile Cataract.—A case of this nature is reported by Sidney Stephenson, whose patient was a woman aged fifty-five years. She was, when first seen, wearing glasses—11 D. spherical, which she had obtained from an optician. Right vision: fingers at one meter and Jaeger No. 1 at 8 cm.; left vision: fingers at 4 meters and Jaeger No. 1 at 4 cm. The vision of the left eye was improved to 1-6 normal with a-9 D. spherical lens. The tension of the eyeballs was normal. The right crystalline lens was opaque in its deeper parts, with a posterior polar opacity. The left lens exhibited opaque striæ and also a posterior polar opacity. "Floaters" were present in the vitreous humour of each eye. Eight years later the patient was seen again. Upon examination, with the right eye vision was equal to counting fingers at 35 cm. and No. 4 of Jaeger's type could be read at 8 cm The vision of the left eye with a + 10 D. lens was ⅔ normal and with a + 14 D. lens the smallest type on Jaeger's card could be read. A nearly mature cataract existed in the right eye. In the left eye the anterior chamber was deep, the pupil clear and black, the iris sluggish and tremulous, and the tension normal. With the opthalmoscope the dislocated lens was found to be lying in the lower part of the vitreous chamber. The patient was seen for the third time, two years later. Upon examination the pupil of the right eye was found to be clear and black, the iris tremulous, the anterior chamber deep, and the crystalline lens dislocated into the lower part of the vitreous chamber. Tension was normal. Sight with a + 9 D. lens was ⅔ normal and with a + 12 D. lens the smallest print could be read.

British Medical Journal, April 26, 1902.

Kernig's Phenomenon.—J. Rutter Williamson has met with a case in which all the classical symptoms of early spastic paraplegia were present, in which the typical Kernig's sign was noted. The man had no history, nor did he present any symptoms of having had any meningitis.

Two Cases of Acute Intestinal Obstruction Successfully Treated with Quicksilver.—These cases are reported by J. McKean Harrison. The first patient was a man of sixty years, whose condition was most serious. There was constant vomiting, hiccough, and great abdominal distension, weak and running pulse and dry tongue. He was given ½ lb. of metallic mercury and 1 gr. of opium was administered every four hours. His condition gradually improved. The mercury came away ten days after it was given. He made a good recovery. The second patient was a man of eighty years, suffering from acute intestinal obstruction. He had ½ lb. of mercury and [illegible] every four hours. By the twelfth day after [illegible] the [illegible] away, and in about a month the patient's condition was most satisfactory.

The Seton in Migraine and Allied Affections.—[illegible] reports the case of a laborer aged twenty-five who had suffered from headache as long as he could remember. This affection was extremely severe and persistent. The seton was inserted [illegible]. From that time to this report [illegible] four months he has had not one single headache, and that after a heavy meal. He has become bright and active and is back at his work. The seton is changed fortnightly, and the wound is dressed with one layer of [illegible] a day. The writer thinks that [illegible] by counter-irritation.

Observations on Caisson Disease and Its Prevention.—A. H. Mac [illegible] says that a considerable proportion of [illegible] men are, on examination, not considered fit to work in compressed air. The greatest care is necessary in the selection of men for this work. Prevention consists in great part in supplying plenty of fresh air, in maintaining a uniform temperature, and in the careful selection of the workmen. It has been conclusively established that an undue proportion of carbonic acid gas in compressed air causes an increase in the number of cases of caisson disease. As to the treatment, [illegible] are better than opiates, and in cases of severe pain, cannabis indica gives great relief. Potassium citrate, potassium acetate, and ammonium acetate are good in the convalescent stage or when the pain diminishes, but may be given from the first with good results. By far the best treatment is the medical lock, into which purified air should be pumped until the pain goes, then the pressure is very gradually reduced. All new hands should be examined after work each day for a week, and the [illegible] going off and that going on twice each week, and those who are indisposed, kept above ground till well. Should the pulse have a high tension the man should be kept under observation every day, and should there be a [illegible] sound in the heart, or reduplication of the second sound, he should be suspended altogether.

Deutsche medicinische Wochenschrift, April 10, 1902.

Granular Degeneration of the Red Blood Cells.—Waldemar Loewenthal reports the results of his experimental observations upon the basophilic granular degeneration of the red blood cells. As is well known, this condition is regularly observed as one of the earliest manifestations of lead poisoning. Loewenthal endeavored to ascertain the action of tin and cerium upon the red blood cells of the guinea-pig. Accordingly several of these animals were inoculated (intraperitoneally) with ascending doses of chloride of tin and sulphate of cerium. It was at once apparent that great care must be exercised in judging the changes thus produced, as guinea-pigs are extremely susceptible to these metals, and it is very difficult to control. The susceptibility varies greatly in different guinea-pigs, and furthermore according to the external conditions under which they have been placed. Granular degeneration of the red blood cells is produced in guinea-pigs by intraperitoneal inoculations of tin chloride and cerium sulphate, but it cannot be definitely stated that such is due to the poisonous action of these metals. Guinea-pigs are in a certain sense unsuitable for such experiments, since normally they show more or less granular degeneration of the erythrocytes. When confined in dark places or exposed to damp weather they habitually show such a degeneration, which more or less completely disappears when they are placed under more favorable surroundings. Observations upon the erythrocytes of man under similar conditions are extremely desirable.

Paratyphoid.—Albert Brion and Heinrich Kayser report a case which was clinically one of typical typhoid fever with the presence of the roseola. That, however, the clinical picture was not due to the bacillus typhosus is shown by the facts (1) that no positive Widal reaction was ever obtained, and (2) that a bacillus was isolated from the blood which was agglutinated by this blood in a 1 to 1000 dilution. It is, therefore, certain that this bacillus was the cause of the infection. In many respects this bacillus resembles the bacillus typhosus, and is hence to be classified among the so-called paratyphoid bacilli. In addition to being present in the blood, the bacillus was also found in the urine and vaginal secretion, and in the latter the gonococcus was also found. The bacillus is actively motile, does not retain Gram's stain, and gives rise to characteristic typhoid colonies on agar or gelatine plates. The stab growths in gelatine are also characteristic of the bacillus typhosus. It ferments maltose, dextrose, and lactose with the formation of gas. Less gas, however, is produced in lactose media than in those which contain maltose or dextrose. Saccharose and starch are not fermented. It possesses no hemolytic power upon dogs' blood. It is markedly pathogenic for white mice and guinea-pigs and less so for rabbits. It may be considered as identical with the bacterium typhi (type A) of Schottmüller, since it is agglutinated by the anti-serum of that microorganism in a 1 to 1000 dilution. It was not agglutinated by an experimental anti-typhoid serum in any dilution. The study of this case shows that in all cases of clinical typhoid fever which fail to show a positive Widal, the agglutinating power of the blood against the various species of paratyphoid bacilli should be ascertained. Only in this manner can the frequency of paratyphoid infections be ascertained.

Cholelithiasis.—J. [illegible] draws attention to the value of electricity in the diagnosis and treatment of this disease. In the diagnosis the presence of tenderness in three locations, either singly or combined, is of great importance. These locations are (1) the region of the gall-bladder, (2) the inferior border of the liver, (3) a more or less circumscribed area immediately to the right of the tenth to twelfth dorsal vertebra. In many cases tenderness at one or more of these locations may be demonstrated by the use of ordinary palpation or percussion, but in other instances the tenderness can only be elicited by the use of the electrical current, either faradic or galvanic. Here the degree of tenderness, and consequently the intensity of the process, can be accurately ascertained by beginning with a very weak current and gradually increasing its strength until tenderness is produced. It is certain that for this purpose electricity is a much more delicate test than either palpation or percussion. While it is not true that the tenderness here described is pathognomonic of cholelithiasis, yet its presence is of great aid in the differential diagnosis between cholelithiasis and such conditions as right floating kidney, gastric hyperacidity and gastric ulcer. Furthermore, it is a reliable indicator with respect to the value of the treatment which is being employed. Such tenderness regularly diminishes as the case proceeds toward recovery. Dietetic measures and the prolonged use of small doses of Carlsbad waters constitute the most beneficial form of treatment. In general all fats should be excluded from the diet, which should especially be non-constipating in character. Massage is always contraindicated in this disease. It is certain that it may induce attacks of biliary colic in cases where they have not previously been present, and may increase the intensity and frequency of attacks in cases in which such have formed a part of the clinical picture.

The Tuberculosis Question.—Arnold Heller as the result of his experience, takes exception to the views recently expressed by R. Koch with respect to the non-transferability of bovine tuberculosis to man. Three possibilities exist for the acquirement of tuberculosis by man: (1) It may be hereditary; (2) It may arise from the ingestion of the meat or milk of tubercular animals; (3) Direct or indirect contagion may take place from man to man. With respect to the third possibility, it is, of course, absolutely certain that it is responsible for the presence of a large amount of human tuberculosis. With respect to the occurrence of hereditary transmission, it may be said that, while such is possible, yet it is certainly of very little practical importance. The observation of animals (guinea-pigs) which are very susceptible to tuberculosis shows that this must be the case. All the guinea-pigs of the Pathological Institute in Kiel are descended from two of these animals, which by inoculation were rendered tuberculous in 1890, before their first offspring were born, yet tuberculosis has never appeared spontaneously amongst these animals except in two short periods between 1895 and 1897, when the development of the disease in such as were affected could be definitely traced to other causes. In substantiation of his views regarding bovine and human tuberculosis, Koch lays great stress upon the fact that intestinal tuberculosis is a rare condition. Proper observations, however, show that such is not the case. It is well known that tuberculosis follows diphtheria quite frequently. Post-mortem examinations were made in 714 fatal cases of diphtheria, in order to ascertain whether or not tuberculosis was present and if so, to determine its location. Of these 714 cases 140 were tuberculous, and of this number 53, or 37.1 per cent. showed primary intestinal tuberculosis either alone or in combination with tuberculosis of the mesenteric glands and other organs. Contrary to the general opinion, intestinal tuberculosis is more frequent in adults than in children. Of 836 fatal cases of tuberculosis in adults, in 62.9 per cent. intestinal tuberculosis was present at autopsy, while in 419 similar cases in children an intestinal tuberculosis was found in only 40.5 per cent. In the decision of this question cases are of great importance in which it can be practically proven that bovine tuberculosis has been directly transmitted to man. A case of this character is here reported in which a man tatooed the backs of both his hands, using for this purpose cow's milk. Lupus soon developed at both of the places which were so tatooed. It is interesting to note that the tatooing was practised on different days, and that milk from the same source was always used, and, furthermore, that the lupus developed simultaneously in both locations. The microscopical examination of the lupus tissue showed the presence of characteristic giant cells, but no tubercle bacilli were found.

Berliner klinische Wochenschrift, April 7, 1902.

Menière's Disease.—Josef Gescheit reports a case of this disease, which is of especial interest as showing the beneficial results of galvanization. The patient was a man forty-eight years of age, who had suffered from this disease for four years. During this time, the attacks varied in frequency and intensity. Frequently there had been as many as seven attacks daily. Latterly, the attacks had markedly increased in severity. The treatment had been very diversified, but had been entirely without avail. Gescheit at first advised the use of quinine, but as no result was obtained this was soon discontinued. The galvanic current was next applied by means of Erb's electrode, the positive pole being applied to the tragus of the affected ear and the negative pole over the cervical vertebra The strength of the current employed was from 3 to 4 milliampères. The single sittings lasted about three minutes and were repeated every second day. During the applications the patient experienced increased dizziness and some nausea. Following them, however, the patient was much improved. Twenty-five to thirty sittings sufficed to bring about a complete cure with the exception of a slight ringing in the ear. The attacks, however, did not reappear, and the patient was able to resume his ordinary occupations, which he had not been able to pursue during the preceding four years.

The Unity of Pathogenic Streptococci.—Alexander Marmorek has endeavored to solve the question of the unity or multiplicity of the various so-called species of streptococci upon biological grounds. The different streptococci which he examined were obtained from cases of erysipelas, puerperal fever, scarlatinal angina, pneumonia complicating measles, pustular and phlegmonous lesions, diphtheria, tuberculosis and influenza. For comparison he also tested two species obtained from horses, one from a case of petechial fever, and the other from a case of glanders. There are two biological characters which are common to all the varieties of streptococci obtained from man, but which are not possessed by those obtained from horses. These are first their hæmolytic action upon rabbit's blood and second their inability to grow in their own culture filtrates or those of other pathogenic streptococci. With respect to the first characteristic it may be said that the hæmolytic power of the various pathogenic streptococci against rabbit's blood varies with the virulence of the microorganism, and also in some measure, according to the source from which it is obtained, but it may be definitely stated that this is a biological character possessed by all pathogenic streptococci. The inability of certain pathogenic streptococci to grow in the culture filtrates of other pathogenic streptococci is one of the strongest points in favor of the theory of the unity of the streptococcus. In no single instance was the author successful in his endeavors to cultivate one streptococcus in the culture filtrate of another. In his immunization experiments Marmorek was able to protect rabbits against one species of streptococci by the inoculation of the antiserum of another species. The quantity of the anti-serum necessary to do this, however, varied greatly in different cases. This variation is not to be ascribed to a fundamental difference in the species, but to the various external influences to which they have been subjected (symbiosis, etc.). As the result of this work the author believes that there is no scientific ground for maintaining the multiplicity of species of pathogenic streptococci and regards them as all of the same derivation.

Berliner klinische Wochenschrift, April 14, 1902.

Temperature Crises in Tabes.—Bruno Oppler reports the case of a man, forty-one years of age, who first came under observation in 1897. A history of syphilis was absolutely negative. For some years the patient had been addicted to the excessive use of alcohol and tobacco. For ten years previous rheumatic pains had been experienced, at intervals, in the lower extremities, and for eight years indefinite stomach disturbances had been present. In May, 1897, a typical gastric attack occurred. Examination at that time showed the reflexes to be intact. No fever was present in spite of light chills and an accelerated pulse. These attacks were repeated at six or eight weekly periods, and a probable diagnosis of periodical hypersecretion was made. In the summer of 1898 the patellar and pupil reflexes disappeared, the pains in the lower extremities became more severe, and ataxic symptoms developed. In February, 1899, the symptom-complex of the crises suddenly changed in that the stomach symptoms were greatly lessened in intensity and great prostratiom with violent chills and fever appeared. During these attacks the axillary temperature rose to 40.4° C., and in the course of a few days gradually subsided to normal. No spleen enlargement or herpes labialis were present. These attacks were repeated seven times between February and October, 1899. Since that time, as the result of treatment, principally phenacetin, protargol and various water cures, the patient has somewhat improved, although the ataxic symptoms have remained in *statu quo.* Malaria, osteomyelitis, etc., may be absolutely excluded, and it may be regarded as certain that the crises are tabic in nature. The case is very similar to one reported by Pel in the *Berliner klinische Wochenschrift,* June 26, 1899, and is of interest, since, with this exception, the condition has not been previously described.

Is the Gonorrhœa of Prostitutes Curable?—In answering this question Thomas von Marschalko relates his personal experiences. In 161 cases of gonorrhœa in prostitutes, the urinary passages were involved in ninety-nine, the glands of Bartholini in thirty-seven, and the uterus in 108. In the first class of cases (the urethral) the earliest disappearance of the gonococcus after the beginning of treatment was five days, the latest 117 days, and the average twenty-eight days. In the second class of cases the earliest disappearance was seven days, the latest ninety-two days, and the average twenty-seven days. In the third class of cases these periods were thirteen, 153 and fifty-six days respectively. The treatment in the first two classes of cases consisted in the local use of 1 to 2 per cent. nitrate of silver solution or 1 to 5 per cent. solution of protargol; occasionally in stubborn cases 10 to 20 per cent. protargol-glycerin solutions were used. In the cases of uterine gonorrhœa 5 per cent. solutions of natrium lygosinatum were chiefly used, although a few were treated with 5 to 10 per cent. protargol solutions. Two intrauterine treatments per week were given. Such treatments were, as a rule, well borne, although occasionally in the beginning slight attacks of uterine colic were produced The danger that tube infection will result from the intrauterine applications is insignificant, and is not to be considered in such a condition as uterine gonorrhœa to which tube infection is a natural sequel. The opposite position taken by most gynecologists is due to the fact that the majority of cases which come under their observation are in women who have borne children, and a large number of these have had disease of the uterus and its appendages previous to the gonorrhœal infection. The majority of the author's patients were young women who had never been pregnant. From the above results it is seen that the gonorrhœa of prostitutes is by no means incurable, when treated along the proper lines, at least in so far as the disappearance of the gonococci is concerned.

French and Italian Journals.

Tuberculous Hepatitis.—Charles Laubry speaks of the treatment of this affection, which he considers very grave. Prophylactic treatment should consist in abstinence from alcoholic drinks, from excess of all kinds, and in intestinal antisepsis (lavage of the stomach and purgatives). In the chronic form an absolute milk diet is indicated,and recourse may be had, but with precaution on account of pulmonary tuberculosis, to iodide of potassium. In the acute form, digestive symptoms are combated by applications of ice, hemorrhages by chloride of calcium and delirium by chloral. Stimulants are indicated at times. —*La Tribune Médicale,* April 9, 1902.

Contribution to the Study of Hysteria.—Lefèvre concludes that the manifestations of hysteria are of an infinite variety. There may be deafness, buzzing in the ears, blindness, narrowing of the visual field, aphonia, anæsthesia, paralysis, etc. The combination and distribution of these various troubles may follow a thousand different ways, without relation to anatomical facts, without accordance, even, with physiological laws. If, then, troubles the most bizarre are dependent upon hysteria, it is always well to think of this affection when in the presence of symptoms which are very difficult to explain, and which do not seem related to any definite malady. Hysterical phenomena do not correspond to any organic lesion They are dependent upon a psychical trouble and upon auto-suggestion. The hysterical patient is often cured of his trouble by sudden emotion, especially surprise.—*Archives Médicales Belges,* March, 1902.

Premature Infants.—L. Hahn enumerates various characteristics of the premature infant and discusses the affections to which it is peculiarly liable. The body is small, the skin is thin, soft, and of a uniform redness, often having a yellowish tinge, and transparent. The nails are thin [illegible] March 29, 1902.

Kernig's Sign in Sciatica.—V. D. Magni reports the case of a patient suffering from sciatica who gave to perfection the sign which Kernig claimed to be pathognomonic of meningitis. Incomplete extension of the lower extremities assumed by the patients when put in a sitting posture, although when recumbent they present no contractures of the muscles of the limbs. The position of flexion once taken it is found that if the trunk is held firmly it is impossible to extend the limbs no matter how great the force exerted. They can, however, be extended if the trunk is at the same time freely able to bend backward. The author concludes that this sign cannot be pathognomonic of meningitis, since it has been found in persons in whom the meninges are intact.—*La Riforma Medica*, April [illegible], 1902.

Malignant Pustule Treated by Sclavo's Serum.—Claudio [illegible] reports a case in which a cure followed the use of this serum. The remedy seems to act in two different ways, according to the nature of the case. In adynamic cases without fever the serum causes a rise in temperature as an expression of the exertions put forth by the organism for the overcoming of the infection; while in cases in which the strength has been kept up the fever falls as the immediate effect of the increase of the natural defensive power. "By means of the serum," says Sclavo, "we place the organism in about the condition of an animal which has been properly vaccinated, and in which the bacillus of malignant pustule is destroyed at the seat of injection without causing general disturbance or affecting the temperature."—*La Riforma Medica*, April 11, 1902.

Splenectomy and Talma's Operation in Banti's Disease.—[illegible] describes the case of a woman who was apparently in the last stages of Banti's disease, or splenomegaly with cirrhosis of the liver. The author is convinced that a poison is formed in the spleen which causes the hepatic affection in such cases, for which reason he determined to remove the spleen, in spite of the grave condition of the patient, owing to emaciation, and an enormous amount of ascites, which was quickly reproduced after paracentesis. On the other hand, the blood was in good condition, the patient young, and the liver, in spite of its lesions, had not lost its normal size. He therefore operated, associating splenectomy with Talma's procedure for inducing deviation of the portal circulation. The result was extremely satisfactory, the patient has improved in health and vigor, and the ascites has not been reproduced in even a slight degree.—*La Riforma Medica*, April 1, 1902.

Rectal Alimentation in Certain Cases of Typhoid Fever.—A. [illegible] reports a case of typhoid fever in which every symptom pointed to a fatal termination of the disease. It was found impossible to give nourishment by the mouth, as each attempt brought on violent nervous crises; therefore rectal injections of concentrated broths with [illegible] yolk of egg, [illegible], and marsala were given two or three times a day. In about ten days the patient was somewhat improved, so that a few spoonfuls of marsala and of water could be given by the mouth. The rectal feeding, together with these few spoonfuls of liquid nourishment, was continued for twenty-five days, at the end of which time the patient was able to take nourishment in the usual way. Recovery followed. The author reports several other cases, in all of which he is absolutely convinced that the rectal alimentation was the exclusive factor in recovery.—*La Riforma Medica*, April 12, 1902.

Progressive Hemiplegia in a Patient Who Had Had Syphilis; Discovery of Cerebral Glioma at Autopsy.—Tolot reports the case of a patient of thirty years, who, about two years before entering the hospital, had suffered from a prolonged sore throat accompanied by an eruption, and swelling of one of the labia majora. The iodide treatment dispelled these phenomena. The diagnosis of syphilis appeared certain. The patient entered the hospital with a left hemiplegia, the beginning of which had been noticed about four months before. The development had been progressive. There had been no headache, nor any other phenomena of that nature. There was a certain degree of cerebral torpor, and the patient laughed without any reason, but there was no actual delirium. The entire left side was affected. The reflexes on each side were exaggerated. It was difficult to make all of the desired examinations on account of the unwillingness of the patient. There had been no vomiting. The splanchnic organs revealed nothing abnormal. Iodide of potassium was administered, but without avail. The patient died in about three weeks. At autopsy the left hemisphere appeared normal, but in making sections of the right hemisphere, two neoplasms were discovered of the size of large nuts. They were just under the lenticular nucleus and on the inner side at the level of the internal capsule there was a softening which had certainly been the cause of the hemiplegia. The new growth was hard and grayish. Although syphilis had not shown itself for two years one could but think of gumma, especially as the growth was not soft as gummata are apt to be. Histological examination, however, showed it to be a glioma. The latter test alone was able to clear up the diagnosis, as the clinical phenomena were not definite enough to be convincing.—[illegible] *Médical*, April 6, 1902.

Archives of Pediatrics, April, 1902.

A Case of Mongolian Imbecility.—Philip F. Barbour reports the case of a negro boy of eleven years, first seen four or five years ago, presenting the typical appearance of Mongolian imbecility. Thyroid treatment was given, but there has been no change in his mental condition. The author thinks it probable that the very rapid growth occurring under treatment may be ascribed to the thyroid medication.

Enlarged Bronchial Lymph Nodes in Children.—Alfred Friedländer says that the child who, without being positively ill, is never very well, who catches cold easily, is subject to "stomach cough," whose digestive functions are not good, whose appetite is capricious, and who does not gain in weight regularly, steadily, even though slowly, is the child upon whom should rest the suspicion of incipient tuberculous adenitis. The essentials of treatment are good food, good air and rest. The special idiosyncrasies of the individual child in respect to food must be studied, but in general terms it may be said that milk, eggs, meat, and bread, with a great abundance of butter, should form the main articles of diet. Excess of starchy foods must be avoided. Fruits, light desserts, and if there is no constipation, pure stick chocolate may be allowed. Salt baths are advisable, and rest in pure air will be better than too much exercise. Three drugs are of especial value, the iodid of iron, cod liver oil and creosote.

Pyloric Stenosis in Infants.—In the treatment of this affection, E. W. Saunders recommends belladonna, bromides, and chloral to overcome the violent contractions of the pylorus. Opiates should not be given. Treatment of the secondary gastric irritation consists in washing out the stomach and giving it a rest. Rectal feeding should be resorted to from time to time, and for twenty-four or more hours, nothing but water given by the stomach. When food by the mouth is again allowed, the stomach should be washed out occasionally to remove a possible residuum of undigested food. The diet of the child should consist of food which forms no coagulum in the stomach. Whey or peptonized milk, or both, is the best. The end to be accomplished is hypertrophy of the gastric wall without dilatation, hence the quantity of food should not be large. If, in spite of all rational treatment, the child fails, surgical intervention must be advised.

A Note on the Treatment of Gastrointestinal Hemorrhage in the Newly Born by Suprarenal Extract.—L. Emmett Holt was called in consultation in regard to an infant which, when sixteen hours old, began to vomit blood, and continued to do so at intervals of a few minutes. One grain of saccharated extract of suprarenal gland was ordered every hour, suspended in water. This was given regularly for six or eight hours, and then the dose was reduced to half the quantity, and the intervals were made longer. Twelve hours after beginning the treatment, the hemorrhages entirely ceased, and did not recur. The entire period of the hemorrhages lasted about thirty hours. By the fifth day the minute hemorrhages beneath the skin had disappeared, as also those on the mucous membrane of the mouth. The subsequent history of the child was uneventful. The solution of the active principle, adrenalin, is possibly to be preferred for internal use to the powder, as one grain of the extract makes rather a large dose for a young infant. The local effect of the extract seems to be proved in the case reported, but whether any marked effect upon general hemorrhages is to be expected by its internal administration is problematical.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Seventeenth Annual Meeting, Held in Washington, D. C., April 29 and 30, 1902.

J. C. WILSON, M.D., OF PHILADELPHIA, President.

FIRST DAY.—TUESDAY, April 29.

The meeting was called to order in the New Willard Hotel at 10.15 A.M., by the President, Dr. J. C. Wilson of Philadelphia.

President's Address on Medical Societies.—Dr. J. C. WILSON in this address gave a sketch of the growth of medical societies of the country. One of the great pioneers was the Massachusetts Medical Society, founded in 1781, while the organization of the American Medical Association in 1847 marked a new era in this movement. The speaker said that association had done a great and good work, and had encouraged its many members to loftier aims, yet, from the very nature of its organization it possessed inherent defects. Being based on political lines, it had frequently been swayed by political influences, and the scientific work had suffered in consequence. Reorganized, as it now was, the routine and political work was more widely separated from the scientific, thus leaving the sections untrammeled, and with its exceedingly valuable journal the future of that association was certainly promising. But because of the defects of medical societies of this class there had sprung up others of a more distinctively scientific character. Among the earlier ones founded on these lines were the American Surgical Association, the American Gynecological Society and the Association of American Physicians.

Comparative Toxicity of Ammonium Compounds: a Study of Autointoxication.—DRS. K. RACHFORD and W. H. CRANE of Cincinnati presented this paper, which was read by Dr. RACHFORD. Their method of investigation consisted in the injection into ordinary house mice of a sufficient quantity of a 5 per cent. solution to produce death. Sodium chloride, nitrate and phosphate were found not to be tonic, while the same ammonia salts of the acid ion were quite tonic. When the tonic dose was not quite sufficient to produce death, the convulsive movements and gasping respiration gradually subsided. The body acids were excreted as ammonia compounds. The ammonium ion when combined with an organic acid lost, for the most part, its toxicity. The ammonium salts of acetic, lactic, sarcolactic and Beta-oxybutyric acid were comparatively non-tonic. The sodium was not drawn upon very much to neutralize the acids in the body except when introduced as medicine. When given medicinally it might be used to protect the ammonia in the tissues. The sodium salts were not directly responsible for any of the symptoms observed in acid intoxications. It was possible that potassium played an important rôle in the neutralization of acids. The potassium ion possesses about half the tonicity of the ammonium ion when combined with the same inorganic acid. The symptoms of potassium poisoning in mice were rapid and labored breathing, terminating in asphyxia.

Acid Ions.—Sulphuric, hydrochloric, nitric and phosphoric acids were comparatively non-toxic, and were found not to act as direct symptom producers in acid intoxications. On the other hand, ammonium chloride, sulphate, phosphate, and nitrate were comparatively toxic, but this was due chiefly to the contained ammonium. In an advanced stage of diabetes mellitus there might be as much as fifteen or twenty grams of betaoxybutyric acid excreted in combination with five grams of ammonia without producing symptoms of ammonia poisoning. When lactic acid was combined with a non-toxic base, such as sodium, the resulting salt was non-toxic; hence it was evident that lactic acid itself was not toxic. When combined with ammonium the toxicity of the ammonia base was diminished Oxalic acid, when combined with ammonia, made a very poisonous salt. Oxalic acid poisoning was largely due to the oxalic acid itself and not to the base with which it was combined. Carbonic acid was an acid ion constantly found in the body. Carbonate of ammonia was converted in the body into urea.

DR. C. A. HERTER of New York thought one was not justified at the present day in attributing to the salts of ammonium any considerable degree of toxicity in the organism. When the salts of ammonium were excreted by the urine in excess, the evidence was that this increased excretion depended primarily upon the presence of acid. No other pathological conditions were known in which the ammonia excretion was increased. So far as he knew, whenever the ammonia excretion was augmented it was due either to the presence of organic acid in excess or to the use of those varieties of food containing phosphorus or sulphur, which, as in the case of milk and meat, were readily oxidized into phosphoric acid and into sulphuric acid respectively. It would be better, he thought, to make these comparisons of the toxicities of the different salts of ammonium.

An Estimate of the Amount of Toxin in the Blood of a Horse Infected with Tetanus.—DRS. B. M. BOLTON and CARL FISCH of St. Louis were the authors of this paper. They had been unable to find the toxin in either the cerebrospinal fluid or the blood of any of the children dying of tetanus in St. Louis. The first horse was inoculated with a small amount of earth containing the tetanus germs, yet there were no signs of infection. At the end of twenty-one days the animal was again inoculated, this time with a larger quantity of the earth. The animal showed no signs of illness until the sixth day. Two days before death the blood contained the greatest quantity of tetanus toxin. In another horse, in which death occurred on the sixteenth day, no tetanus toxin was found in the blood until four days before death. The blood from all the horses was drawn at intervals of twenty-four hours after inoculation, and the amount of toxin in the serum determined by injection into guinea-pigs and other small animals. A great variation in the quantity of toxin was noted.

DR. A. C. ABBOTT said that last winter he had examined the blood of a child dying of tetanus. The blood was collected from the heart within twenty-four hours of death, and injected into white mice, which are very susceptible to tetanus. The injection was entirely negative.

The Etiological Significance of the Acid-Resisting Group of Bacteria, and the Evidence of Their Botanical Relationship to Bacillus Tuberculosis.—Drs. A. C. ABBOTT and N. GILDERSLEEVE presented a communication on this subject. They stated that these organisms were strikingly like tubercle bacilli, but the latter would withstand the effect of acid decolorizers very much longer than any of the members of the group under consideration, and the use of very much stronger acid. They had found that practically the whole group were almost instantly decolorized by the usual acid mixtures employed for decolorization in connection with examinations for tubercle bacilli. This was true not only of the old nitric acid decolorizer, but when the now popular 5 per-cent. solution of sulphuric acid was employed. As a result of their observations, practically all of the characteristics of tubercle had been found, but not all of the characteristics in any one nodule. There was no special evidence of caseation, and none whatever of dissemination, but as the nodule continued to grow, there would ultimately result organization or suppuration—in other words, the picture was less like that of an ordinary tubercle as of the growth of an actinomycotic nature. In the acid-resisting organisms it was the rare exception to find any involvement of the lungs by these nodules, though they were praclesions uniformly present in the kidneys. In the very earliest stages of their development one might confound these growths with tubercle, but this should not occur in the more advanced stages, either in gross or microscopical examination. They had noticed within these growths certain organisms which were not like the tubercle bacillus. In practically all of these nodules one or more of these actinomyces could be seen. As these acid-resisting organisms were found quite commonly in butter, inoculation experiments were undertaken to determine the significance of these organisms. Six calves received injections of 1½ to 18 c.c. of an emulsion-suspension of these organisms directly into the jugular vein. The organisms were not recovered from these animals, even as long as twenty to thirty-three days after the inoculation. Inhalations into the lungs gave typically negative results. There was nothing to indicate that these microorganisms were harmful. With regard to their relation to the tubercle bacillus, it was known that under certain modes of growth organisms resembling actinomyces would develop. Animals that had been inoculated with very large numbers of these organisms had, in no instance, given a reaction with tuberculin. The trend of present opinion was that the term "bacillus" was a misnomer not only for the so-called tubercle bacillus but for the acid-resisting organisms and the actinomyces, and that they should all be called actinomyces.

Dr. S. FLEXNER of Philadelphia said that he had had an opportunity of examining the specimens made by Dr. Abbott, and there could be no doubt that the nodular growths referred to were not true tubercles. They contained not infrequently giant cells, but these were of the type generally regarded as foreign-body giant cells, and not the giant cells typical of tuberculosis. The whole structure of the nodule reminded one of granulation tissue. A few years ago he had studied the lesions produced by the pathogenic yeasts, and the growths formed by these organisms were pseudo-tubercles, and closely resembled the nodules under discussion in the paper. The absence of softening and of fibrous tissue around the lesion in actinomycotic tubercle should serve to distinguish it from the true tubercle.

Dr. ABBOTT said, in reply to questions, that the only certain way to get results with animals was to select small animals and make injections directly into the circulation, and not merely under the skin. They had found it so easy to differentiate these acid-resisting organisms by the old and well-known methods of decolorization that they had not extended their observations to other and newer modes of preparation.

Histological Alterations of Cytotoxinic Intoxication.—DR. SIMON FLEXNER of Philadelphia was the author of this paper. He called attention to the fact that it had been demonstrated by Bordet, Ehrlich, Metchnikoff and others that many kinds of body cells when injected into animals of another species—alien animals—gave rise to the production of cytotoxins, agreeing in many physiological properties with bacterial and other toxins. They seemed to act specifically upon cells of the kind from which they had been derived. The injurious action of these cytotoxins upon cells had been studied as yet very little histologically. It had occurred to the author that new light might be thrown upon this interesting subject by an investigation of their action upon the lymphatic system, as the lymphatic organs seemed peculiarly well adapted for demonstrating lesions of a toxic nature. For many months he had experimented on guinea-pigs, using the rabbit as a source of toxin, but had found that rabbits are so exceedingly susceptible to infection that these observations were conducted with great difficulty. More recently he had experimented with geese. The lesions produced in the lymphatic glands were general throughout the body, and they agreed quite exactly with the lesions of such an infection—for example, in experimental diphtheria. The general swelling of the lymphatic glands and the changes in the centers of these glands were almost exactly similar in the two classes of experiments. Apparently the nonlymphatic organs were not attacked. He had kept under observation for some time animals in which these toxins had been produced by introducing the cells of one animal into other animals of the same species. It was possible that such an infection would throw light upon our knowledge of various infectious processes.

The speaker said that some years ago the subject of terminal infection had been presented by him to this association. The question had been raised as to whether any changes took place in the "receptor" and the "complement." The work had been carried on during the past year with some interesting results. In these terminal infections it was found that there was in the great majority of cases a marked reduction in the "complement," or an absence of it, so far as demonstrable from its action on the typhoid bacillus and the colon bacillus. Susceptibility to bacteria meant, therefore, that for some reason or other the means for destruction had disappeared.

Dr. A. C. ABBOTT said that in animals which had been given alcohol for three or four weeks there had been noted a marked loss of weight and marked interference with nutrition. There was also a reduction in the complementary substance of from 15 to 20 per cent. This he mentioned because of its bearing on the statement made by Dr. Flexner regarding terminal infections.

A Study of Bacterial Cells.—DR. V. C. VAUGHAN of Ann Arbor, Mich., presented in this paper a review of the following investigations, which had been carried on for the most part, in his laboratory: "The Toxicity of the Cell of the Colon Bacillus and the Production of Immunity with the Colon Toxin," by L. M. Gelston and C. E. Marshall; "The Chemistry of the Colon Cell," by Mary F. Leach; "The Chemistry of Sarcines," by May Wheeler (Rockefeller scholar in Hygiene); "The Toxin of the Cell of the Diphtheria Bacillus," by L. M. Gelston; "The Pigments of Certain Bacteria," by A. J. Detweiler; "The Action of the Sarcines and the Micrococcus Prodigiosus on Animals," by A. J. Detweiler; "The Chemistry of the Anthrax Bacillus," by J. Walter Vaughan. In this work great help had been derived from the use of the tank which he had devised for growing germs on a very large scale. This same process had enabled him to study and collect the pigments formed by certain bacteria.

Dr. VAUGHAN exhibited three handkerchiefs, two of which had been beautifully dyed by the pigments from the bacillus prodigiosus. An extended series of experiments in immunization had been carried out on animals. From immunized rabbits he had obtained a serum which would immunize other rabbits. The great desire among bacteriological chemists had been to find the antitoxin of anthrax. Dr. Vaughan exhibited a powder composed of the broken-down cellular elements of anthrax. This powder, in doses of 200 to 250 milligrams, would kill a guinea-pig weighing 250 milligrams.

Dr. Vaughan then went on to review the theory of Ehrlich, and to show that it might be replaced, in part at least, by another theory, which would explain more satisfactorily the results obtained. The work already done indicated that bacterial cellular toxins contain two or more toxic groups, one of which is much more readily split off than the other. This explained the decrease in toxicity, which had been generally observed in solutions of bacterial toxins on standing. The work also suggested a new theory concerning the action of antitoxins. The author held that this work might modify our conceptions of what constituted life in its unicellular manifestations.

Some Effects of Tobacco on the Tissues of Rabbits.—Dr. I. ADLER of New York presented this preliminary communication. The experiments upon which the paper was based were still in progress, and were far from being completed. The animals were kept in box stalls, the floors of which were covered with excelsior, as the rabbits would not eat this. Each rabbit was fed on fresh cabbage, mixed with varying quantities of infusion of tobacco. This infusion was made from very cheap cigars. At first each rabbit received daily a pint of infusion made from two cigars, but gradually this pint of infusion was made to represent the strength of three, five, six and even eight cigars. He now had under observation one rabbit which had been fed on tobacco infusion for six months, it was fat and apparently well. None of the animals had died under this treatment. After feeding in this way for three weeks none of the organs, in the rabbits then killed, was found to be diseased. An animal killed after two months and a half of such feeding, and while apparently in perfect health, showed no pathological changes in any organ except the liver. This organ was larger and paler than normal, and felt gritty when cut with a knife. The lobulation was very marked, and there was a decided interlobular proliferation following the course of the portal vessels and bile ducts. Not the slighest change in the parenchyma could be detected. A rabbit killed after four months presented the same general appearance, though the liver was harder and more granular. Microscopical examination showed the interlobular process to be more advanced. These experiments, though incomplete, seemed to bring out at least one fact, *i. e.* that one tonic substance, alcohol, acting with extreme chronicity, exerted an effect upon the interstitial tissues, at least in the early stages, without affecting the parenchyma of the liver, or being associated with lesions of the other organs.

Dr. J. G. **Adami** of Montreal thought there was something paradoxical in these observations. It was an established fact that the so-called proliferative bile ducts in cirrhosis were not true bile ducts, but modified and altered liver cells at the edge of the lobules. Dr. Adler had admitted that there was proliferation of the bile ducts, and as this was really the result of change in the liver cells he could not wholly accept the author's conclusions.

Dr. C. A. **Herter** of New York said he would be loath to transfer the results of these experiments on animals to the human subject on account of the very large doses employed.

Dr. **Adler** said that he had been misunderstood. He had not attempted at all to produce cirrhosis of the liver, nor to draw any analogy between these observations and the processes going on in the human subject. Whether the changes he observed were true bile-duct proliferations or not, he would only say that he would be happy to show his microscope slides to Dr. Adami. He could vouch for the fact that the liver cells had not been at all affected. He wished again to say that the paper was not at all upon liver cirrhosis.

A Case of Hæmatoporphyrinuria.—Drs. J. Tyson and A. C. Crofton of Philadelphia reported this case. The patient was a woman of fifty years, who had been taking from twenty to sixty grains of sulphonal every night for several years in order to produce sleep. Last November she had consulted her physician because of severe abdominal pain and tympanites. She had been first seen by Dr. Tyson on December 7, and at that time, in addition to the symptoms just noted, there were dry tongue and a feeble frequent pulse. An examination of the urine in the sick room showed it to be a dark red fluid. It was carefully studied by Dr. Crofton. Dr. Tyson said that sulphonal had been introduced into practice in 1888, and that since that time there had been reported about one hundred cases of hæmatoporphyrinuria. Four specimens of this patient's urine had been examined on the four days following the cessation of the use of sulphonal. None of the specimens contained bile pigment or bile sugar. The fourth contained only a trace of hæmatoporphyrin, and the urine was of nearly normal color. The presence of hæmatoporphyrin had been detected both by chemical and spectroscopic tests. It was estimated that about one-seventeenth of the hæmoglobin in the body of this patient had been destroyed and excreted in the form of hæmatoporphyrin. It was natural, therefore, that this great loss should have given rise to a severe grade of anæmia.

Dr. C. F. Withington of Boston reported a similar case, occurring in a woman of thirty-eight. Her urine was known to have been normal previously. Trional was given in doses of thirty grains and resulted in scanty urine and hæmatoporphyrinuria, the patient dying a few days later.

Dr. M. Allen Starr of New York said that his clinical assistant had reported a case in which trional had caused both hæmatoporphyrinuria and multiple neuritis.

Pneumococcic Arthritis.—Dr. J. B. Herrick of Chicago presented this paper. He said that this complication was relatively rare, being present about once in eight hundred cases of pneumonia. Up to 1901 only thirty-one cases had been reported, but to this number he was able to add several others, including three of his own. It had been noted by several observers that traumatism and previous disease of the joints, such as gout, were predisposing causes. Pneumococcic arthritis often did not develop until fifteen or twenty days after the crisis. Experimental work corresponded well with this clinical fact, for it had been noted experimentally that pneumococcic arthritis was most apt to occur when attenuated cultures of the pneumococcus were used or the animals were relatively immune. The resemblance of pneumococcic to gonorrhœal arthritis was striking. In both, the larger joints, especially the knee, were involved, and the affection was usually monoarticular. The prognosis was generally bad because of the severity of the primary pneumonia or of the accompanying bacteriæmia, or because some other vial organ was simultaneously affected. The treatment was necessarily surgical in most instances, but he would suggest that a radical operation was not always necessary, as there was a certain tendency toward spontaneous recovery or recovery after aspiration or simple incision.

Dr. William Osler of Baltimore said that there were three groups of cases of pneumococcic arthritis, viz.: (1) Those of localized arthritis without other lesions; (2) Those following or associated with pneumonia, and (3) Those in which the arthritis is associated with a general pneumococcus septicæmia. A case was reported in which several joints were affected and turbid fluid was withdrawn by exploratory lumbar puncture. This fluid, as well as the blood, contained numerous diplococci. The autopsy showed meningitis, along with suppurative arthritis of the knees and ankles.

Dr. J. H. Musser of Philadelphia reported a similar case.

The Pathology of Herpes Labialis and of Herpes Zoster Occurring in Acute Croupous Pneumonia.—Dr. W. T. Howard, Jr., of Cleveland, O., was the author of this paper. He reported two illustrative cases. Histological study of the Gasserian ganglia showed hemorrhage into the ganglion on one side, with cellular proliferation, compression and destruction of some of the ganglion cells. In the second case there was a marked herpes zoster in the sixth dorsal region on the left side. Sections of the left eleventh dorsal region at autopsy showed congestion of and hemorrhage into its capsule. In one small area were a few disintegrated ganglion cells with slight round-cell infiltration. Degenerations could not be demonstrated in the nerve, posterior roots or spinal cord. The author concluded that, as the lesions in the [illegible] and in the skin in cases of herpes of the [illegible] and [illegible] of herpes zoster occurring in [illegible] were the same, and as they had the same pathology as ordinary herpes zoster, it was probable that the various forms of herpes are [illegible].

Dr William H Thomson of New York remarked that his clinical experience indicated that the recurrence of herpes labialis was of favorable import.

A Case of Hodgkin's Disease with Recurrent Fever.—Dr H F Vickery of Boston reported this case. The patient was a girl of nineteen who was under observation seventy-eight days and who presented six febrile periods of six to eight days, with febrile intervals of about the same length. There was no reaction to tuberculin or other distinct evidence of tuberculosis. The diazo reaction was absent at first, but subsequently became positive. One of the glands excised presented the structure of a mixed-cell sarcoma. Death occurred in coma. No autopsy was obtainable.

Dr M Allen Starr of New York said that although Dr Musser had reported last year a large number of cases this disease was not generally recognized by the profession. Last November he had been called in consultation by an excellent practitioner to see a patient who had been under his care for some time with some nervous symptoms. The patient was a woman of thirty-six, of tuberculous family history. In 1899 Dr W T Bull had removed a number of glands from the neck, which, on examination, proved to be tuberculous. In May, 1900, she had begun to suffer with febrile attacks, lasting from seven to ten days. These attacks were followed by a non-febrile period lasting from ten to forty days. It was thought that physical exercise or excitement, or painful menstruation, was responsible for these attacks of fever. They continued up to the time of his seeing her in November, 1901. In October Dr Bull had removed some glands from the other side of the neck. These had been examined by a careful pathologist, who reported only a connective tissue hyperplasia. Examination of the patient showed a slight splenic enlargement, but nothing was found in the lungs, or any evidence of enlargement of the glands back of the sternum. On December 24, when the temperature was 102° F, the hæmoglobin was 90 per cent. The red blood cells were 4,640,000 and the white cells 5,800.

Dr Francis P Kinnicutt of New York said that he had seen this patient last February. Since February 15 there had been three periods of pyrexia of ten to thirteen days' duration, and three intervals of five to eight days. The temperature rose slowly, as in typhoid fever, and descended slowly. The spleen was distinctly enlarged, hard, and more or less nodulated. The liver was enlarged, and from the dulness there was apparently an enlargement of the mediastinal glands. The blood count was very much the same as in the case reported by Dr Vickery. There were two views regarding lymphadenoma; one that it was a distinct infection, the organism of which had not yet been discovered, the other, that a number of diseases clinically the same, but pathologically different, had been grouped together under this name.

Dr J H Musser of Philadelphia said that the large proportion of cases called Hodgkin's disease were really examples of tubercular adenitis. Unless inoculation experiments were made, it was hardly right to exclude tuberculosis as a cause. The term pseudoleukemia, was no more satisfactory than to call all diseases having fever, but in which there is an absence of the features of typhoid fever, pseudo-typhoid fever.

Dr William Osler of Baltimore referred to a case which clinically appeared to be Hodgkin's disease, but which proved to be lymphoma. A differentiation could be readily made by histological examination.

Splenic Anæmia and Its Varieties.—Dr William Osler of Baltimore read this paper. He said that many of the cases had lasted from ten to twelve years. The enlarged spleen was the most marked feature on physical examination. In some cases the size of the spleen had remained unchanged for a number of years. In none of his cases had the lymph nodes been enlarged. The blood changes were those of a chloro-anæmia. In some of the cases the red cells had been above four million and the hæmoglobin below 50 per cent. There had been an exceedingly low leucocyte count in six or eight of the cases. In ten hemorrhages from the stomach had been marked and a characteristic feature, though this was much larger than the usual percentage. In some instances the hemorrhages had recurred at intervals of a few months for a period of many years. When it was remembered that at least 40 per cent of the blood from the stomach was discharged into the portal vein, it was not a matter of great surprise that hemorrhages should frequently come from the stomach. Pigmentation of the skin had occurred in seven of his cases. In the late stages there had been a change in the size of the liver, sometimes an increase and sometimes a diminution in size. Jaundice might be an early symptom, and was not necessarily associated with cirrhosis of the liver. Recurrent attacks of anæmia and jaundice and ascites had marked a recent case of this disease. The anatomical changes had been stated to be characteristic, but in only one of the three spleens that he had examined had there been present the changes supposed to be characteristic of the disease. At the Johns Hopkins Hospital they had operated upon three cases, two of which had terminated fatally. The only point in favor of the view that the spleen might have something to do with this disease was the fact that a certain number of cases had recovered after the removal of the spleen. He was inclined to think that the etiology was unknown, and that the enlargement of the spleen was only one feature. He had received from members of this association reports of forty-two cases, showing that the disease was not so very uncommon.

Dr. J H Musser of Philadelphia reported two cases, one of them having been under observation seven years.

Dr R C Cabot of Boston reported eight cases, occuring in adults. All of them had enlargement of the spleen, while in none were the lymph nodes enlarged. Three out of the eight had profuse vomiting of blood. In two cases there was enlargement of the liver, and one of these had ascites as well. None of the cases showed any pigmentation of the skin. There were also two cases of polycythæmia associated with enlargement of the spleen. The speaker said he saw no reason for the term splenic anæmia. All of his cases had been chronic, but in very few of them had it been possible to fix the beginning of the disease. The blood examinations had not been characteristic. There was just as low a percentage of hæmoglobin in other cases; on the other hand, the extremely low white count noticed in four out of the eight cases was peculiar, but not enough to justify looking upon this as a special kind of anæmia. There were many cases of secondary anæmia of unknown cause, and also many cases of enlargement of the spleen of unknown origin. In some of the cases the association of enlargement of the spleen with leukæmia was probably only a coincidence.

Drs Billings and Stengel also reported cases.

Dr Stiles of the Department of Agriculture said that he had been studying lymphatic disease in animals. In one outbreak occurring among cattle he had been able to trace it to a parasitic infection of the walls of the fourth stomach. The parasites studded the wall so thickly as to suggest trichinosis. He had been struck by the fact that, in the cases so far reported to-day, nothing had been said about any examinations having been made of the gastrointestinal tract. He would suggest that in obscure cases of anæmia careful search should be made for intestinal infections. He had in his possession specimens of parasitic infection of this kind coming from Virginia, Texas, and Porto Rico.

Dr William H Thomson of New York said that in his own experience with these cases of enlarged spleen the autopsies had yielded extremely varied results. If the function of the spleen was so subordinate that this organ could be removed without sacrificing the life of the person, it was hardly reasonable to suppose that primary disease of the spleen should give rise to such profound constitutional changes.

A Case of Albuminuria Associated with Pernicious Anæmia.—Dr. H. F. Vickery of Boston reported this case. The patient was a man of forty-seven with albumosuria and the general course of a progressive anæmia. However, there were only two megaloblasts present to seventeen normoblasts. There were no symptoms or external evidence of bone disease, and an *x*-ray examination was negative. The case terminated rather suddenly by an attack of syncope. No post mortem was obtained.

Dr. J. H. Musser reported a similar case, in which the chief feature of interest was an extraordinary fatty degeneration of the muscles.

Dr. A. Jacobi of New York said that in grave anæmias, and particularly in pernicious anæmia, albuminuria was not at all uncommon.

Angiomyositis.—Dr. W. S. Thayer of Baltimore read this paper, reporting a case in which there were repeated attacks of œdema and hemorrhage into the different muscles. The case apparently corresponded with those classified by Lorenz as polymyositis hæmorrhagica, the angiomyositis of Lepine. The etiology of polymyositis was apparently yet in doubt. The case reported by him occurred in a man of thirty-four years. The first thing noticed by the patient was a sudden snapping in the muscles of the arm while lifting. This was followed by pain and a discoloration, as if a vein had burst. This cleared up, but in the course of a few months these signs and symptoms recurred without apparent cause. Last fall a similar condition had suddenly developed on the dorsum of the left foot. With the exception of these attacks the man had been perfectly well. In the attack in which he had been seen by Dr. Thayer the region of the biceps muscle on the arm was the seat of discoloration, œdema and dull pain. There was no great tenderness on deep pressure. On incising what appeared to be muscle there had escaped about 150 c.c. of blood-stained fluid. Sections from the biceps muscle were exhibited under the microscope. The history did not favor the theory of the infectious origin of this myositis.

Dr. R. C. Cabot asked what was the reason for believing that this was a myositis.

Dr. A. Jacobi said that the simple form of myositis was known to be of traumatic origin—for example, those cases occurring in the newly born in the sternomastoid muscle. Again, traumatic hæmatoma of this muscle was sometimes seen in boys who had been flying kites. A multiple myositis like the one described in the paper was more commonly seen by general practitioners than by hospital physicians in cases of purpura. Purpura appeared to him to be a microbic disease, and in many cases of this affection there was a marked sensitiveness of the muscles, lasting sometimes for weeks or months. He thought most of these cases of myositis should be considered as only a part of the purpura.

Dr. Thayer said that there must be some doubt as to the proper classification of a case of the kind he had reported, because there could be no question that in the pectoralis major and the deltoid there was hemorrhage into the muscle substance associated with swelling and slight tenderness, and that these were followed by subsequent atrophy. The history would suggest some form of angioneurotic œdema or some disorder of the purpuric group.

A Report of the Cases of Thermic Fever Treated at the Pennsylvania Hospital in the Summer of 1901.—Drs. M. J. Lewis and F. A. Packard of Philadelphia presented this report. There were thirty-one women and sixty men, and in 50 per cent. of all the cases there was an alcoholic history. In many cases abstraction of blood had been practised, the quantity withdrawn varying from seven to twenty ounces. In no instance did it do any harm, and in many instances it was followed by marked improvement. Saline infusion into the median basilic vein proved useful in some instances.

Dr. Frank Billings of Chicago cited a case in which the temperature, on admission to hospital, had been too high to be measured by the ordinary clinical thermometer. After a cold bath the man had gone into collapse, but had been revived, and then the temperature had quickly risen from 100° F. to 110°. The man had eventually recovered.

Dr. J. H. Musser said that of six cases, having a temperature between 109° and 115° F., two recovered, and in these saline solution had been injected.

Dr. F. A. Packard of Philadelphia said it was the opinion of all of those who had seen the saline solution used that more persons had been saved by this procedure than would have been saved without it.

A Clinical and Experimental Investigation of the Value of Gelatin as a Hæmostatic.—Drs. A. Stengel and D. L. Edsall of Philadelphia presented this communication. The authors stated that, from their experiments with gelatin in typhoid fever, they were of the opinion that more grave cases of this disease had recovered than would have been expected to recover without the gelatin, and that the experiments should encourage more extensive observations in this field. Their studies had been undertaken with the object of ascertaining whether the action of gelatin was because of its acidity, because of its calcium content, because of its ability to agglutinate the corpuscles, or because of its effect in slowing the peripheral circulation. The direct injection of gelatin into animals did not show any tendency of the blood to coagulate, but all such experiments had shown a tendency to coagulation in small vessels and to hemorrhages in the lungs and intestinal tract. Their own experiments had revealed the production of an intense congestion at the base of the lung. They had proved that gelatin was normally an acid substance. Used with salt solution, gelatin was found to cause rapid and striking agglutination of the blood-corpuscles and the formation of small bodies resembling blood plaques. The viscosity of the gelatin itself seemed to be largely responsible for these results, as a similar action was observed when tragacanth was substituted for the gelatin. Ferric chloride, cuprous sulphate, alum and zinc sulphate produced a similar effect on the blood-corpuscles, while weak solutions of ammonium chloride, calcium chloride, bichloride of mercury and chloroform water had no such effect. None of the cases studied showed any increase of already existing kidney disease, or any development of such disease; nevertheless gelatin and similar substances were excreted as such—that is, as foreign bodies. No difficulty was experienced in feeding gelatin to the typhoid patients, except that it sometimes caused nausea when persisted in in considerable quantities.

Dr. M. H. Fussell of Philadelphia said that he had only used gelatin in one case of hemorrhage in typhoid. The hemorrhages had lasted for three days and the patient was greatly exhausted thereby. He fed the gelatin to the patient, and also injected it under the skin. Within a very few hours after beginning the use of the gelatin the hemorrhage had stopped. Each injection of gelatin under the skin was followed by a slough of the integument, about one and a half to two inches in diameter.

Dr. George L. Peabody of New York said that he had experimented with a 1 per cent. solution of gelatin, and had found that if the solution were not thoroughly sterilized it would produce redness and pain, but that this would quickly disappear under the use of an ice bag. When the solution was sterile it caused no such trouble.

Dr. S. J. Meltzer of New York said that in cases of typhoid fever subcutaneous injections or other slight abscess frequently led to local infection, even though done under aseptic precautions.

Dr. Frank Billings of Chicago said that after having tried the gelatin injections in typhoid fever for the control of hemorrhage he had given it up because of the great pain caused by the injections. He had always used sterile solutions, and had observed no sloughing. Moreover, the results of such gelatin injections had been so variable as to lead him to think that the good results occasionally noted were largely coincidences. A colleague had been studying the coagulability of the blood, and had found that if one or two grams of chloride of calcium were given by mouth two or three times a day the coagulability of the blood would be markedly modified in the course of a few weeks. He had made use of this medication for the purpose of bringing a patient with cholæmia into proper condition to allow of operation without danger from excessive hemorrhage. He had done this repeatedly, and had been profoundly impressed with the power of chloride of calcium to increase the coagulability of the blood.

Dr. Tyson said he had used gelatin in quite a number of cases of typhoid fever, and had found it impossible to draw any conclusions as to its value. On the other hand, he had practised injections of gelatin in a case of aneurysm for fifty days in succession, using 10 c.c. at a time, without producing any unpleasant or other local effects. He had been surprised that it could be kept up so long without harmful results, although it certainly caused moderate pain.

Dr. Stengel said that several cases had been reported of tetanus following the injection of gelatin, but this could hardly arise from the use of the gelatin as such, because it was well known that tetanus bacilli did not grow readily on gelatin. It was an interesting question to decide whether gelatin possessed any agglutinating power other than what it derived from its calcium content. As calcium salts were not readily or rapidly absorbed from the intestinal tract they should, on theoretical grounds, be used hypodermically; nevertheless, they could be used with perceptible effect by the mouth in moderate doses three times a day. The injections were certainly painful, but he had never seen any sloughing, having been careful always to make use of sterile solutions.

Hæmolymph Glands. A Lantern Slide Demonstration.—Dr. Simon Flexner, in the unavoidable absence of Dr. A. S. Warthin, presented Dr. Warthin's lantern slides. He said that, since 1890, four or five descriptions of the hæmolymph glands had been published. Apparently the pathology of these glands had been entirely uninvestigated until Dr. Warthin had undertaken their study. This investigator's attention had been called to the glands first by the presence in the prevertebral fat of man of certain glands, which were redder than normal and different in structure from the ordinary lymph glands. Dr. Warthin then took the first eighty autopsies available, and searched for these glands. About half of these were studied in the region of the vertebral column, the mesentery and the region of the kidney. In the other cases a search for these glands was also made in the mediastinum and about the neck. He found that they were extremely numerous, and of all sizes, some being scarcely visible, and others quite large enough to be readily seen microscopically. It was difficult, however, to distinguish them from ordinary lymph glands, because after death they were deprived of their blood. Dr. Warthin then studied them in sheep, where they are very prominent and very numerous. In the human subject there were about one of these to ten of the ordinary lymphatic glands. Since then the investigation had been directed toward the elucidation of their structure. He had discovered two kinds, one of which the spleen was the type, and the other of which the marrow might be considered the type. In the two extremes the spleen and the marrow were quite closely reproduced. Two general forms were described, one in which the glands were rounded, and the other in which the glands were flattened. In the former there was a well-developed capsule. The elongated glands were more likely to be of the marrow type, while the globular ones were of the splenic type. The capsule penetrates the interior of the gland, constituting the trabecular network. Perhaps the chief histological distinction was the presence of blood where, in the other glands, lymph was to be found. These glands are made up of reticulated or so-called adenoid tissue, and the spaces are filled with blood containing, perhaps, an excess of white cells. It was doubtful whether the sinuses in the spleen all connect with a closed vascular system, and this point was likewise obscure in the hæmolymph glands. The collections of lymphoid cells in these glands had been compared with the lymphoid nodules of the spleen, but it was only exceptionally, as Dr. Warthin had shown, that there was a central vessel corresponding with the vessel of the Malpighian body. It was found that the large cells filled themselves with red corpuscles, very much as was observed in the spleen. In addition, pigment was found either free or contained in phagocytes. Dr. Warthin was of the opinion that, under normal conditions, they had nothing to do with blood formation, although under pathological conditions it was probable that they might act vicariously in connection with blood formation.

Mitosis in the Circulating Blood.—Dr. Barnes presented on behalf of Dr. George Dock of Ann Arbor a series of slides illustrating this subject.

Report of the Presence of Anguillula Aceti in the Urine of Two Patients Mistaken for Strongyloides Intestinalis.—Dr. Frank Billings and Dr. J. L. Miller of Chicago made this report, and exhibited lantern slides. The case had first been regarded as one of filaria sanguinis hominis, but repeated examinations of the blood, made at night, failed to show the presence of filaria, and then it was discovered that the worm was too large to belong to this group. It was finally identified as an intestinal parasite, known as strongyloides intestinalis.

Dr. Stiles of Washington, D. C., said that the report failed to state whether the urine had been drawn by catheter or had been sent to the physician in a bottle that had contained vinegar. He had met with a similar case, in which the same erroneous diagnosis of filaria sanguinis hominis had been made. On taking a specimen of the urine by catheter none of these worms was found, but they were present in the vinegar used in the patient's house. There was just a bare possibility that the worm had been taken into the mouth in vinegar and had wandered from the stomach to the bladder, but the doctrine of chances made this view exceedingly improbable. He thought it was not impossible that in Dr. Billings' male patient the worm had been transmitted from the female, just as occurs in the case of the trichomonas vaginalis. It was well to recollect in this connection that some women were in the habit of endeavoring to prevent conception by the use of douches containing vinegar. The two spicules found on the worms in Dr. Billings' case marked the worm as the ordinary vinegar eel. The two cases reported to-night, and the one he had referred to as having occurred in Washington, were the only ones of the kind with which he was familiar, though various similar worms had been found in the urine. He had recently published a key by which the differential diagnosis of these worms in the urine could be readily made.

Dr. A. Jacobi of New York said that in a girl of thirteen he had at one time found in two specimens a peculiar worm. He had examined many specimens of the urine since that time, but only on these two occasions had it been found with an interval of about four weeks.

Vaccine Bodies in Cases of Smallpox.—Dr. James Ewing of New York spoke of the vaccine bodies which he had studied carefully during the past year, and dwelt particularly on a special form lying in vacuoles in the cells and exhibiting peculiar staining properties. His remarks were illustrated by lantern slides, and were presented as an introduction to a paper on smallpox, to be presented to the association at a later session. The number of vaccine bodies was found to bear a pretty close relation to the severity of the hemorrhagic lesion. His study of this subject had comprised about thirty cases, and it was not until he had reached the twenty-eighth case, one of exceedingly severe hemorrhagic smallpox, that he discovered that red cells enclosed in epithelial cells might undergo transformations which rendered them indistinguishable from vaccine bodies. The typical vaccine body, treated by ordinary methods, always picked out the basic dyes, but he had found another type of vaccine bodies taking by preference the basic dyes, but capable of being stained by acid dyes also. In specimens hardened with formalin it was almost impossible to find these vaccine bodies, but if hardened with formalin-Muller solution, and stained with eosin, they could be readily demonstrated.

In answer to a question from Dr. W. H. Welch, Dr. Ewing said that he had not made any study of the vaccine bodies in the cornea of a rabbit, because his attempts to inoculate the cornea had, for some unexplained reason, been unsuccessful, although the same vaccine virus had readily produced typical lesions when inoculated into the skin of the rabbit.

SECOND DAY—WEDNESDAY, APRIL 30.

The Prognosis of Pleurisy with Effusion.—Dr. R. C. Cabot of Boston presented this communication, which was based on a study of 300 cases. He had experienced the usual difficulties in tracing the cases, only one-tenth of them having been found by letter. Then, by calling at the original addresses and making inquiries of the neighbors, many more had been traced. Some help had been derived from the records of the department of vital statistics, and from those of the overseer of the poor. He thought this method of tracing patients very useful and satisfactory. He had traced 152 cases. of this number eighty had remained in sound health. Those in sound health for fifteen to twenty-one years were twenty-one; those for ten to fifteen years, twenty-three; those for five to ten years, thirty-six; in other words, 80 per cent. of the cases of uncomplicated serous pleurisy were in good health for over five years, and 90 per cent. in fair health for a period of from two to five years after the pleurisy. Fifteen per cent. of the cases had developed sooner or later a demonstrable tuberculosis of the lungs, but in only 3 per cent. had tuberculosis manifested itself within two years after the pleural effusion. The attack of tuberculosis in these cases was, as a rule, mild and of slow progress, death not occurring for five years or more after the pleurisy in half of the cases developing tuberculosis. Nevertheless a very rapid form of tuberculosis might develop many years after the pleurisy. There had been in this series two such cases developing ten or fifteen years after the pleurisy. A study of the clinical records of the whole group showed that of those remaining in perfect health for five years or more only one-fourth gave a family or past history of tuberculosis, while of those known to have become tuberculosis, two-thirds had a marked family history of that disease. A careful history was, therefore, of great importance in making the prognosis of a case of pleural effusion. On the other hand, the physical signs in the course of convalescence from the pleurisy was in no respect different in the cases in which tuberculosis subsequently developed from those which remained in good health. The history was, therefore, of greater importance than the physical signs. Reaccumulation of fluid immediately after tapping had been rare, occurring in only 1.3 per cent. of the series. Among the fourteen patients who, after recovering from the pleurisy, died of some other disease, not one developed a disease which could be reasonably considered as connected with the pleurisy. In conclusion, the speaker called attention to the fact that no attempt had been made to discover what percentage of the cases were due to tuberculosis. So far as his statistics went, they might all have been of tuberculous origin. He only desired to call attention to the fact that the outlook was bright in cases of pleurisy not having a family history of tuberculosis, and that even if pulmonary tuberculosis developed subsequently, the type of the disease was unusually mild.

Dr. William Osler said that these figures were very much more favorable than those formerly given by Dr. Bowditch.

Dr. Thomas Harris of Manchester, England, said that he had been interested in this paper because he had been under the impression that the prognosis in simple serous pleurisy was much graver than these figures would lead us to believe; certainly the statistics in England were very much more unfavorable. Of course, these cases just studied were mixed cases, and it was difficult to separate the tubercular from the ones which were perhaps not tubercular. In England pleurisy was looked upon with suspicion by the large life insurance companies, who made it a rule not to accept as insurance risks any person who had been ill with pleurisy within five years. In view of the figures just presented it would seem probable that this rule was too severe and too much in favor of the insurance companies.

Dr. A. Jacobi said it was exceedingly common to find in general practice persons presenting the physical signs of a pleurisy that had probably occurred many years previously. This would seem to support the accuracy of the encouraging statistics presented in this paper.

Dr. V. C. Vaughan said that these figures seemed to him to be a little too rosy. There were 300 cases, only 152 of which had been traced. On account of the long period covered by the investigation, he thought it reasonable to assume that most of the 148 cases that had not been traced were dead.

Dr. Cabot, in closing, said that he had examined the records of one thousand autopsies at the Massachusetts General Hospital, and had compared them with the clinical histories. This showed that in 25 per cent. there was an obliterating pleurisy without any clinical record; hence it was reasonable to assume that a large number of persons ill with pleurisy recover. The deaths had been pretty evenly distributed through the two decades, as had also the cases that had been traced; hence there was no good ground for assuming that most or all of the cases that he had failed to trace had terminated fatally.

A Clinical Study of Cases of Empyema Based on the Bacteriological Findings in the Exudate.—Drs. C. F. Withington of Boston presented this communication, which was based upon 135 cases of empyema occurring in the Boston City Hospital in the last six years. There were twenty-eight cases giving pure cultures of the diplococcus lanceolatus, of which eight died; there were thirty-five cases of streptococcus infection, with nine deaths. The staphylococcus cases showed a higher mortallity than the streptococus cases. The average time at which pus had been detected after the onset of the pneumonia was tweny-five days. Tuberculosis was known to be present in about twenty cases. Operation was done in 155 cases. Of the twenty non-operative cases, ten died. Some of the cases were unsuitable for operation, because they were either recovering or were too far advanced. About one-half of the operative cases were irrigated one or more times after the operation. The mortality in the whole series of cases was 29 per cent. The mortality in the streptococcus cases alone was twenty-six; in the cases of combined infection with the streptococcus and the lanceolate coccus [illegible] per cent of the cases having the streptococcus associated with other organisms than the lanceolate coccus, [illegible] per cent, and to the pure lanceolate coccus cases, [illegible] per cent.

Dr WILLIAM H WELCH [illegible] experiment in determining whether the organism was due to the streptococcus or the diplococcus lanceolatus. There was an intermediate group in which there was a point that made it impossible to make a positive diagnosis without a careful morphological examination together with animal inoculations. A limited experience with the methods employed by Dr Hiss in the laboratory of Dr Prudden had led him to think that these were of great value in this connection.

Dr T. MITCHELL PRUDDEN of New York said that he had come to regard many of the earlier statistics as not very reliable so far as they endeavored to distinguish between the lanceolate coccus and the streptococcus.

Dr HENRY KOPLIK of New York said he was surprised at the large proportion of metapneumonic cases among the adults. He thought it possible that in some of the streptococcus cases if the fluid had been centrifuged tubercle bacilli would have been found. In fully 90 per cent of his own cases of empyema in children the disease had been metapneumonic.

Dr WILLIAM OSLER asked if Dr Withington had any figures pointing at the very great increase of empyema following pneumonia during the past ten years. Very marked evidence of this kind had been collected at Guy's Hospital. These statistics showed that the number of such cases there had been doubled, and he thought the experience of most physicians here bore out the view that empyema cases of this kind were very much more common than formerly, probably because of the prevalence of grip.

Dr WITHINGTON said that his study included only the past six years, or that period in which there was reason to believe the laboratory work had been conducted with the greatest accuracy. The records showed that a very large number of cases of empyema had occurred in the past two or three years.

Spontaneous Non-Tubercular Pneumothorax.—Drs M H FUSSELL and DAVID RIESMAN of Philadelphia presented this paper. They reported three cases of spontaneous non-tubercular pneumothorax and stated that they had been able to find on record fifty-six cases of this kind. In these [illegible] per cent were in females. The pneumothorax might last only a few days, though its effects might persist for a number of weeks. There was a remarkable case on record in which the pneumothorax had lasted for three years. In the majority of cases it occurred after violent exercise. While dyspnœa might be absent altogether, it was usually present, and was of a peculiar character. At the beginning the dyspnœa was urgent on the slightest exertion. Fever rarely occurred. The affected side was usually larger than the other, although in young individuals the opposite was the case. A recurrence of symptoms took place in seven of the tabulated cases, in one instance eight weeks after the first attack. In one remarkable case there were four distinct attacks at intervals of several years.

Dr FRANCIS P KINNICUTT of New York said that he had seen, in the past two years, a single instance corresponding to those reported in the paper. It occurred in a young man who had been seized with severe pain in one side of the chest after lifting a heavy object. He had made a good recovery, and had been discharged from the hospital in four weeks, all of the signs of pneumothorax having disappeared. He had been seen some time afterward and found to be perfectly well. Dr Kinnicut said that he had always believed that in these cases a local tubercular lesion, too small to be detected by ordinary methods of examination, was the beginning.

Dr S SOLIS COHEN of Philadelphia said that one of the cases reported in the paper had occurred in his hospital service, and he would not be willing to say that the case was non-tubercular, although he had failed to discover tuberculosis. In one instance he had made a diagnosis of the pneumothorax in a case in which there was such an enormous cavity as to make it practically a pneumothorax.

Dr F C SHATTUCK of Boston said he agreed with the last two speakers that there was probably in those two cases a tuberculous disease. Within the year there had been at the Massachusetts General Hospital two colored boys with perforating wounds of the abdomen. Laparotomy had been done and tuberculous mesenteric glands discovered. In spite of this, these boys had recovered perfectly. A fact that had been forced home upon him repeatedly in the last few years was the latency or the innocuousness of tuberculosis.

Dr E G JANEWAY of New York said if there was a slight local tuberculous process in the lung in the vicinity of two or three emphysematous blebs, the conditions were favorable for the development of a pneumothorax. Our inability to detect small tuberculous processes in the lungs was well known, often the physician searched in vain for the physical signs of such a process, even after the occurrence of a hæmoptysis had made it practically certain that such a process was present.

Dr G L PEABODY of New York referred to a case that he had seen in Vienna. A child with traumatic œsophageal stricture was having the stricture dilated gradually by bougies. On one occasion there was more than the usual amount of coughing accompanying this dilatation and immediately afterward one side of the chest became full of air. He believed that tuberculosis was likely to be the foundation of pneumothorax.

Dr WILLIAM OSLER referred to a case of pneumothorax occurring in a robust-looking individual. He had given large doses of tuberculin to this man without producing any reaction. His attention had been called in 1873 to a case in which, although the chest was full of air, it was absolutely flat on percussion. He had met with two cases of the kind since that time.

Some Pulsations in the Chest Other Than Aneurysmal.—Dr ARTHUR R. EDWARDS of Chicago read this paper. In it he reported a case of pernicious anæmia, in which there was a diffused expansile pulsation in the chest and upper abdomen without anatomical findings. The clinical diagnosis was arteriosclerosis and abdominal aneurysm pointing toward the diaphragm, or a low thoracic aneurysm and a secondary anæmia. The post-mortem showed degeneration of the myocardium, dilatation and hypertrophy of the left ventricle, a series of yellowish plaques in the left coronary artery, a number of adhesions of the spleen to the abdominal wall and diaphragm, and a marked anæmia of all of the internal organs. The chief clinical interest centered in the presence of marked pulsations, chiefly abdominal, associated with a bruit.

Dr G L PEABODY said that it was common to find extensive adhesions of the left lobe of the left lung and of the spleen without any such pulsations as those described in this case, and hence, this anatomical finding could not possibly explain the occurrence of the pulsations and bruit.

Dr LA FLEUR of Montreal said that he had observed an exactly similar case within the last two months. There was a condition of marked anæmia and signs pointing toward aneurysm of the abdominal aorta. The pulsation was expansile, and there was, in addition, a paralysis of abduction of the left vocal cord, thus pointing still more strongly to the diagnosis of aneurysm. Pulsation in the lower portion of the thorax and the upper portion of the abdomen was notoriously an uncertain sign.

Dr S SOLIS COHEN said that he did not understand that a fluoroscopic examination had been made in this puzzling case reported by Dr Edwards. In a recent obscure case he had found a skiagram useful as a means of positively excluding aneurism.

Dr. Edwards, in closing, emphasized the fact that the pulsation in his case was not merely one propagated from the underlying arteries, but was a dynamic expansile pulsation.

The Healing of Ulcerative Endocarditis.—Dr. J. B. Herrick of Chicago presented a communication on this subject. He said that occasional recovery from ulcerative endocarditis might be expected, because recovery was seen in not a few cases of other forms of septicæmia and pyæmia, even though severe. Moreover, there were many cases on record of recoveries from ulcerative or malignant endocarditis. He had himself seen a case of what he believed to be a pneumococcic endocarditis occurring in a child of three years, in which recovery took place. A very irregular temperature had been present, associated with chills and two crops of petechiæ. After a tedious convalescence the child recovered with a permanent leak at the mitral valve. Post-mortem findings also indicated the possibility of healing of the valvular lesion. It was desirable, therefore, to make an extra effort to differentiate between the different forms of endocarditis, perhaps identifying the special organism at work by means of a blood examination. This would give a sounder basis for prognosis, and would lead to more care and persistence in the treatment, including perhaps the use of anti-streptococcus serum or some of the recently introduced soluble salts of silver.

Dr. W. S. Thayer of Baltimore presented the chart from a case, the symptoms of which justified the diagnosis of malignant endocarditis. At the present time the patient was apparently convalescent. The case had occurred in the service of Dr. Thomas R. Brown. The patient was a young woman, whom she had seen repeatedly during the past eight years. She had a well-marked stenosis and insufficiency following repeated attacks of acute rheumatism. On several occasions she had shown an intermittent fever, lasting for periods varying from a week to a month or two. They had only been able to account for these attacks on the theory that they were dependent upon an acute endocarditis. Last February she had developed an irregular and extremely high intermittent fever, associated with very violent chills, profound anæmia, delirium and great prostration. In addition, there was a rapid and irregular heart action and evidence of a freshly-developed aortic insufficiency. At times the temperature rose to 106° F. These attacks lasted from the latter part of February to April 2, since which time the temperature had been normal or subnormal, and the patient's general condition had steadily improved. There remained well-marked evidence of aortic insufficiency.

Dr. F. P. Kinnicutt spoke of a case that he had seen several weeks after the beginning of a gonorrhœal infection. There had been no cardiac lesion of any kind Following the gonorrhœal infection the man had developed a severe endocarditis, affecting first the aortic, and then the mitral valve. When seen by the speaker there was mitral as well as aortic insufficiency. The man's condition was bad and the prognosis given was absolutely unfavorable. This was two years ago. The man completely recovered in four or five months, and since then had been comparatively well.

Dr. E. G. Janeway reported the case of a man who had come to him every day for a week with chills and a temperature of 105°F. The blood examination showed no malarial plasmodium, but some leucocytosis. The man then presented evidences of marked endocarditis, and was sent to St. Luke's Hospital. He subsequently suffered from nephritis and infection of the lung, but had eventually recovered. There were numerous recorded cases of murmurs due to nothing but anæmia.

Dr. F. C. Shattuck referred to a case in which the sputa had contained enormous quantities of streptococci, and on this account he had used antistreptococcus serum with good result.

Dr. A. Jacobi remarked that recoveries from endocarditis in the child were more apt to be bona fide than in adults, who might have antecedent disease of the heart.

Dr. William Osler said that these cases of recovery belong to a very special group, which he had some years ago denominated the cardiac group. This group was very large, and the endocarditis was of the recurrent form, associated with an old valvular lesion.

The Condition of the Heart in Pregnancy.—Drs. Alfred Stengel and W. B. Stanton of Philadelphia presented this communication. They stated that the notion that the heart was regularly hypertrophied in cases of pregnancy was founded on a study of 130 cases of women dying of puerperal sepsis. The average thickness of the left ventricle in those cases was found to be 1.5 cm. However, in this study no account was taken of the effect of the puerperal sepsis on the heart. The Germans had contended that the supposed hypertrophy of the heart was in most instances spurious, and dependent upon dislocation of the apex of the heart. The authors said that they had taken tracings of twenty-six cases of the heart, and also sphygmographic tracings in women during pregnancy and after delivery. These tracings showed a movement of the apex of the heart downward and inward when the diaphragm was released. In cases in which after delivery there was a large and tympanitic abdomen this downward movement was not so marked, or was delayed. Mention was made of the difficulty of securing an accurate outline of the heart in pregnant women because of the enlargement of the breasts. An enlargement of the heart upward and toward the left had been observed in a very large proportion of the cases, and this they ascribed to an enlargement of the conus arteriosus. After delivery there was no such rapid subsidence of the enlargement of the heart toward the right as there was a return of the apex of the heart to its normal situation. In nine of the eleven primipara examined there seemed to be distinct evidence of enlargement of the conus arteriosus. With regard to the statistics of blood pressure, of which MacDonald of Edinburgh made so much, the authors stated that the blood pressure increased after the patients had been in the hospital for some time. This they endeavored to explain by the skin of the finger becoming thin, soft and tender, and in this way vitiating the readings made with the Gaertner tonometer. The blood pressure before and after delivery was substantially the same. Murmurs were found before delivery in nine out of twelve cases, and after delivery in seven cases. The author's conclusions were, that the outward displacement of the apex of the heart was entirely due to an upward displacement of the diaphragm from pressure; that there was prabably an increase of the size of the right heart and of the conus arteriosus; that the murmur so commonly heard over the heart in the latter months of pregnancy was due to the over-action of the right heart and the distention of the conus arteriosus, and that there was no appreciable difference in the blood pressure before and after delivery.

Dr. M. H. Fussell of Philadelphia was surprised at the large number of cases that apparently had heart murmurs, for, in a fairly extensive experience among pregnant women, he had not met with any such large proportion.

Pancreatic Lithiasis.—Dr. F. P. Kinnicutt of New York was the author of this paper. He said that the literature gave only six cases in which a positive diagnosis of pancreatic lithiasis had been made, or the condition suspected during life. The author then reported a case of pancreatic lithiasis with the recovery of the characteristic calculi from the stools, followed by an attack of cholelithiasis a year later, with the passage of characteristic biliary calculi. The patient was a woman of forty-two, whose family history was unimportant. In

1888 she had suffered from the first attack of pain in the right hypochondrium associated with nausea and vomiting. There were two other attacks, one in 1897 and the other in 1898. Then there were no more until 1901. This attack was very severe. On the sixth day six small calculi were passed in the stools, and analyses of four of the concretions, showing them to be composed chiefly of phosphate of lime, pointed to their origin in the pancreatic duct. The patient had first come under Dr. Kinnicutt's observation in December of 1901. Specimens of both urine and intestinal calculi passed by this patient were obtained and were exhibited. Cultures made from the central portion of one of the recently passed calculi gave no growth. Repeated examinations of the urine failed to show the presence of sugar. The feeding of [illegible] showed normal fat absorption. The presence of, as a rule, large amounts of undigested muscular fibers in the stools, the speaker said, could not be regarded as of much diagnostic importance. The presence of fat in the stools was often due to [illegible] interference with the digestion of fat. A deficient splitting up of the intestinal fat into fatty acids and soaps was, on the other hand, apparently a symptom of great importance. The absence of glycosuria could only be regarded as a negative sign in connection with pancreatic lithiasis, though its presence was a suggestive sign. The absence of cachexia or other signs of a malignant disease of the pancreas in the case reported, and the presence of the other signs and symptoms detailed, seemed to warrant the diagnosis of pancreatic lithiasis.

A Further Contribution to the Subject of Vasomotor Ataxia.—Dr. S. Solis Cohen of Philadelphia presented this paper. He said that since his paper on the subject ten years ago, in which he had reported twenty-four cases of vasomotor ataxia, he had seen, on an average, one case a week of this condition. Certain persons under certain conditions manifest phenomena which in other persons required causes of greater moment to produce—in other words, behind all of the organs there was the man. These phenomena depended upon irregular and sometimes widely distributed contractions and dilatations of the capillaries and the smaller blood vessels. They might be divided into three classes, viz.: (1) Those dependent upon excessive relaxation of the vessels, often associated with impaired cardiac inhibition; (2) Those dependent upon excessive contraction of the vessels, usually with disturbance of cardiac inhibition, but sometimes without definite cardiac phenomena; and (3) Those in which phenomena of the two opposite groups were commingled. The last group was the more common. Graves' disease presented an extreme type of the phenomena of excessive vascular relaxation with paresis of cardiac inhibition. We had been accustomed to hide our ignorance of the nature of many of these cases by designating them idiosyncrasies. Raynaud's disease was an extreme type of vascular constriction. Between these two extremes were many varieties and grades of severity, e. g., simple urticaria, angioneurotic edema, drug idiosyncrasies, hay fever, tendencies to hemorrhages from various organs. Minute cutaneous angiomata and paroxysmal tachycardia. Frequently these persons were hysterical, but this was by no means a constant accompaniment. Far and above these there were many ill-defined conditions arising in response to different stimuli, such as temperature, toxæmias, and emotions. The symptoms of the menopause were essentially vasomotor ataxic in character, but were a transient phase in the devolution of the female. Essential vasomotor ataxia was usually a congenital condition affecting, in different ways, several members of one family. At times, however, they seemed to be acquired as a result of disease or accident.

Dr. Morton Prince of Boston said he would rather call these phenomena the perversions of normal physiological functions. What had been described in the paper was practically what he had described as association neuroses.

Dr. B. Sachs of New York said he could not see the great benefit to be derived from making this large group of cases of vasomotor ataxia. Dr. Cohen had placed at the extremes exophthalmic goiter and Raynaud's disease, and while this speculation was interesting, it seemed to him more important to make concrete studies as to the true nature of these and other diseases.

Dr. A. Jacobi reported a case in which Graves' disease had developed immediately upon a severe fright and mental emotion.

Intestinal Hemorrhage; Its Relation to Duodenal Ulcer.—Dr. Henry Jackson of Boston was the author of this paper. He said that the symptoms of ulcer of the duodenum and of the stomach were so similar that it seemed well nigh impossible to make a positive differential diagnosis. In his own cases hemorrhage had not been a factor of importance, and the hemorrhage was often confusing because it might occur secondary to cirrhosis of the liver. The treatment of the two forms of ulcer were fortunately identical. If the anemia were profound, normal salt solution should be given subcutaneously until the pulse indicated that the crisis had passed. Theoretically this might increase the hemorrhage or start a fresh hemorrhage, but this had not been his experience, and the procedure was most valuable and often life-saving. The author then reported seven cases in which ulcer of the duodenum had been found at autopsy. Four of the patients had died of perforation. In two of the cases the ulcer was of little importance as an etiological factor. In one case hemorrhage was the cause of death. In none of the cases was a correct clinical diagnosis made, nor was it possible in the light of the autopsy. Seven of the patients were men and five women. In four cases there were no symptoms suggestive of gastrointestinal disturbance. Experience seemed to show that large hemorrhages from the stomach or bowel were more likely to originate from an ulcer of the stomach than of the duodenum.

Dr. F. P. Kinnicutt remarked that his clinical experience fully demonstrated the great value of the saline solution, regardless of theoretical considerations.

Dr. William H. Thomson of New York called attention to the fact that ulcer of the duodenum was so much more common in men than in women that it afforded a point in diagnosis. Persistent intestinal hemorrhage with symptoms referred to the abdomen but not distinctly to the stomach, and occurring in men, pointed very strongly to ulcer of the duodenum.

Prognosis and Treatment of Tuberculous Peritonitis.—Dr. F. C. Shattuck of Boston presented this paper, which was based on his experience at the Massachusetts General Hospital for the past ten years. He said that from 1889 to 1900 there had been ninety-eight cases of tuberculous peritonitis treated in the wards of the hospital, of which fifty-seven had been traced. The shortest time that had elapsed was two years, and the longest eleven years. Of the ninety-eight cases thirty-one were males and sixty-seven females, and twenty gave a history of tuberculosis in the family. In sixty-six cases the onset had been gradual; in sixty-three there was fluid in the abdominal cavity. One patient in whom a probably tuberculous peritonitis was diagnosticated received two injections of tuberculin without reaction, and subsequent operation proved the absence of tuberculous peritonitis. Of the ninety-eight cases over one-half occurred between the ages of fifteen and thirty. In eight out of thirteen cases the tuberculin reaction was positive, and in two-thirds of the cases there was no leucocytosis. In fifty-seven of the ninety-eight cases the end result was known. Of these twenty-nine died, of which in twenty-seven the cause of death was tuberculous peritonitis or one of its complications. Roughly, 50 per cent. died after leaving the hospital and 50 per cent. remained well. Seven of the ten cases dying after leaving the hospital lived only a few weeks or months. Tapping was resorted to on the medical division whenever necessary for the comfort of the patient. On the surgical division the treatment consisted in incision and removal of masses from the pleural cavity. Two-thirds of the medical cases were dead, while about two-thirds of the surgical cases had recovered. If after a month or six weeks the patient failed to improve, or even in less time if losing ground, surgical treatment should be tried.

Dr. J. Tyson thought it was hardly worth while to temporize with medical treatment in these cases. He favored the routine use of the tuberculin test in cases of enlarged liver with ascites, believing that many of them originate in a tuberculous peritonitis.

Dr. J. Winters Brannan of New York said that he had looked up the records of Bellevue Hospital for the past ten years, but had found only eighteen cases in which the histories were sufficiently accurate for use. Of this number nine died, or 50 per cent. Of the ten cases treated medically six died.

Dr. Frank Billings of Chicago divided cases of tuberculous peritonitis into three classes, viz.: (1) Those cases in which there was a serous or serofibrinous exudate with a local focus; (2) Those in which there were tumorlike masses or a tuberculous exudate into the glands of the mesentery and omentum, and (3) Those in which there were abhesions between the different parts—a fibrous form. Only in the first-class, in his opinion, was surgical treatment appropriate; in the other cases death almost invariably followed operation. Cases of the second class gave little hope of recovery under any treatment, but the outlook was rather better under medical than surgical treatment.

Dr. S. J. Meltzer of New York reported a case of tuberculous peritonitis now under his observation, which had been cured by laparotomy.

Dr. W. S. Halsted of Balitimore said that he had improved some cases of tuberculous peritonitis having large tuberculous glands. He had been using tuberculin systematically for eight years, and had yet to record a case, proved to be tuberculous, in which tuberculin had failed. When, in a suspected case, no reaction was observed, the reason should be very carefully investigated.

Dr. V. C. Vaughan said he had inoculated a large number of rabbits intraperitoneally. On some of these, after a few weeks, he had performed laparotomy, and in some had found numerous pin-point tubercles on the liver. The wound was closed, and the majority of them lived for about a year. On killing them then, many showed no lesions or the process had been completely arrested.

Dr. A. Jacobi said that as long as tuberculosis was a local process it was likely to heal, whether on the pleura or on the peritoneum. Cases of tuberculosis of the peritoneum unattended by pain or fever he called peritoneal tuberculosis, but when these symptoms were present, he designated them cases of tuberculous peritonitis. The cases of peritoneal tuberculosis should not be subjected to laparotomy, as they often recover under simple treatment or no treatment at all.

Dr. Shattuck, in closing, said that his statistics showed that the mortality in the cases with masses was 30 per cent., and in the cases of fluid without masses, 60 per cent.

A Pathological Study of Thirty Cases of Smallpox.—Dr. James Ewing of New York presented a paper on this subject, and demonstrated illustrative specimens. In the cadaver the trachea usually showed the most severe lesion. Twice the respiratory mucosa had shown a severe and active process when the lesions in the skin were scanty and disappearing. Lobular pneumonia was found to be a common cause of death. Three cases showed acute ulcerative endocarditis. Acute degeneration of the kidney was commonly met with. Aside from petechiæ, no lesions were found in the bladder. Five cases showed numerous variolous ulcers in the stomach. Swelling of the lymphatic structures was a constant change. From these observations it was evident that the first effect of the smallpox poison was the production of coagulation necrosis. In some cases the lesions were those of a diffusible toxin. The congestion attending the local processes was remarkable for its intensity. The exclusive preference of the smallpox poison for the epithelial tissue was a prominent pathological feature. Vaccine bodies were found in all stages of the specific lesions. Cultures were made from the skin in twenty-three cases, and streptococci found alone in seventeen cases, and he was inclined to think that by a better technique it would be found invariably present. The author's conclusions were as follows: (1) The streptococcus completely overshadows any other infecting organism present; (2) It was his belief that it might always be impossible to reproduce the fulminating types of the disease without the aid of the streptococcus.

Dr. W. T. Councilman of Boston said that the study of fifty-two autopsies on cases of smallpox had led him to believe that the most prominent pathological feature was destruction of the polynuclear leucocytes of the blood. The lesions in the bone marrow were totally different from those obtained in any other blood infection. In the septic cases of smallpox one found most extensive necrosis, and a complete absence of polynuclear leucocytes, or, in other words, no barrier to the pathological process. In the hemorrhagic cases this was most marked, and the secondary invasion had usually arisen from the mucous membranes. He was of the opinion that one rarely dies of smallpox *per se*, but from the secondary infections, which paralyze the powers of resistance; in other words, death really occurred from septicæmia. He did not think the various organisms included in the epithelial cells played any part whatever in the disease, except in connection with secondary infection.

Exhibition of Anatomical Lesions of Smallpox.—Dr. W. T. Councilman presented an interesting series of anatomical specimens on behalf of Drs. Magrath and Brinckerhoff of Boston.

Some Experiments on the Nature of Vaccine Virus.—Dr. William H. Park of New York read this paper. He spoke of the use of the monkey to differentiate between smallpox and chickenpox. In no instance had there been any positive result from inoculation with chickenpox, while in every case of inoculation with smallpox the inoculation had "taken." This seemed to him an absolutely safe method of differentiation in very obscure cases. Certain experiments seemed to show that calves could be vaccinated with concentrated, crushed and filtered vaccine virus, but these experiments were not yet complete.

A Case of Osteitis Deformans and One of Hyperostosis Cranii.—Dr. Morton Prince of Boston reported these cases. He took the ground that osteitis deformans is a trophic disorder, dependent upon some lesion of the central nervous system. This view seemed to be supported by autopsies in which the nerves and spinal cord had been carefully examined.

Some Clinical Manifestations of Hepatic Cirrhosis.—Dr. G. G. Sears of Boston read this paper, which was based on eighty autopsies. Alcohol was found to be the most potent factor, while malaria was also an important etiological element. The author concluded that hepatic cirrhosis was in most cases but one effect of a systemic poison. There was no evidence to show that the disease was not always progressive.

Clinical Manifestations of the Early Stage of Cirrhosis of the Liver.—Dr. Frank Billings of Chicago reported in this paper a group of cases presenting anatomical evidence of recent hepatitis. The author attributed the [illegible] clinical manifestations [illegible] resulting from the condition of the liver, and pointed out as a confirmation of the truth of this theory, that the disappearance of the clinical manifestations was [illegible] with the [illegible] state of the liver.

Experimental Glycosuria from Adrenalin Chloride, and Its Relation to Other Forms of Glycosuria Dependent upon the Action of Reducing Substances on the Cells of the Pancreas. Dr. C. A. Herter of New York presented this communication. In it he detailed some experiments that he had been making with applications of adrenalin chloride to the cells of the pancreas. He presented evidence that pointed strongly to the theory that many and probably most forms of glycosuria are due to the action of substances which interfere with the normal oxidations in the cells of the pancreas. The glycosuria following the use of adrenalin appeared to be intimately connected with its reducing action upon the cells of the pancreas. Other substances, possessing strong reducing power, were found to be capable of inducing glycosuria when applied directly to the pancreas.

Officers Elected. *President,* Dr. James Stewart; *Vice-President,* Dr. W. T. Councilman of Boston; *Secretary,* Dr. Henry Hun of Albany; *Treasurer,* Dr. J. P. Crozer Griffith of Philadelphia; *Recorder,* Dr. S. Solis Cohen of Philadelphia; *Councillors,* Drs. Charles G. Stockton and Walter Reed.

Book Reviews.

Traité de Médecine. Deuxième Édition. Publié sous la Direction de MM. Bouchard, Professeur à la Faculté de Médecine de Paris, Membre de l'Institut, et Brissaud, Professeur à la Faculté de Médecine de Paris, Médecin de l'Hôpital Saint Antoine. Tome V., par MM. Chauffard, Brault, et Roger. Paris: Masson et Cie., 1902.

With this volume seven of the ten volumes of the work are completed, volumes VI and VII having appeared previously. In this part are contained treatises on "Diseases of the Liver and Biliary passages" by Dr. A. Chauffard, "Diseases of the Kidneys and Suprarenal Capsules" by Dr. A. Brault, and "Pathology of the Hæmatopoietic Organs and Blood Vascular Glands, Bone Marrow, Spleen, and the Thyroid and Thymus Glands" by Dr. G. H. Roger. These treatises are most valuable contributions to medical literature, dealing, as they do, on subjects of the greatest importance and present interest, and written by men who are known, in France at least, as authorities in their own lines. At the risk of making an invidious distinction between articles all of great merit, we would commend especially the treatise on diseases of the kidneys as one in which the last word has been said that can be said in the present state of our knowledge. But the entire volume is good and compares very favorably with its predecessors in this excellent series.

A Manual of Ophthalmoscopy for Students and General Practitioners. By J. E. Jennings, M.D. (University of Pennsylvania), author of "Color-vision and Color-blindness: A Practical Manual for Railroad Surgeons"; formerly Clinical Assistant Royal London Ophthalmic Hospital, London; Fellow of the British Laryngological and Rhinological Association; Member of the American Medical Association; Member of the St. Louis Medical Society, etc. With ninety-five illustrations and one colored plate. Philadelphia: P. Blakiston's Son & Co., 1902.

This is a small volume of 180 pages, which sets forth the essentials of ophthalmoscopy in an elementary way, and is designed for the use of students and practitioners. One colored plate and ninety-five black and white figures, many of which are original, serve to fully illustrate the text. In the first chapter a short history of the ophthalmoscope, a description of the instrument and a brief discussion of the use of mydriatics are found. Chapter II is devoted to a description of the technique of the methods of ophthalmoscopy. Chapters on "Examination of the Media of the Eye," "The Appearance of the Normal Fundus," "Congenital Anomalies," "Diseases of the Choroid, of the Retina, Retinal vessels and of the Optic Nerve" follow. Illustrations of all of the usual changes in the fundus accompany the text. The work is well suited to fulfil the purpose for which it is designed.

Hygiene for Students. By Edward F. Willoughby, M.D. (London), Diplomate in State Medicine of the London University, and in Public Health of Cambridge University. 561 pages. London: Macmillan & Co., Limited. New York: The Macmillan Company, 1901.

The present volume is really a fourth edition of a work published under the title of "Principles of Hygiene," but differs from the original in many particulars, such as the subject of Sanitary Law, which has been omitted in the present issue, the chemical disposal of sewage, which is dismissed with an unconditional disapproval, and a general revision of what was considered necessary to retain from the earlier publications, together with many additions, which the change in title and advance of knowledge has rendered needful.

The author has rewritten the entire sections on the analyses of milk, butter and water, and in so doing has incorporated what recent experience has taught us to be the most satisfactory and practical methods. The same improvement is shown in the subjects of Demography and Dietetics, both of which are strictly up to date, although concise. At the end of each chapter a synopsis appears with a list of questions, thus making the work more attractive to students, and especially those who are anticipating examinations.

The Healing of Nerves. By Charles A. Ballance and Purves Stewart. 119 pages, illustrated by 16 plates and one figure in the text. London and New York: The Macmillan Co.

The exact process whereby peripheral nerves, after they have been divided, become reunited, has been a subject of considerable controversy. The present research was undertaken with the object of solving some of the problems so raised. In a measure it has succeeded in doing so. Some of the more important conclusions reached by the authors are as follows: In the regeneration of peripheral nerves after the nerve has been divided, new fibers (axis-cylinders, medullary sheaths and neurilemmata) are formed in the distal segment from preexisting cells. The young axis-cylinders and medullary sheaths are laid down in the first instance in the distal segment, and they become attached later to those of the central segment, thereby restoring the conductivity of the nerve trunk. Such views have been advocated by a few investigators; the majority, however, teach that the new axis-cylinders which appear in the regenerated distal segment are direct outgrowths from those in the central segment. The changes which characterize regeneration of a divided nerve differ according to whether or not the proximal and distal segments have been brought into apposition. Within twenty-four hours after a nerve is severed the proximal end of the nerve exhibits a primitive end-bulb, produced by the curling up of the loose ends of the divided fibers. This acts as a scaffold on which the permanent end-bulb is deposited. The earliest signs of regeneration in the distal segment appears after three weeks, many longitudinal spider cells appear in the distal segment and in the intermediate scar tissue, which shoot out young beaded axis cylinders from their opposite poles. These are new axones, which overlap and coalesce with one another. New medullary sheaths appear in about four weeks and inclose the axones. Regeneration of a severed nerve is not brought about by the growth of the proximal extremities of the axis cylinders, but is accomplished by the development from longitudinal chains of cells of axones, which fuse together and become enclosed in medullary sheaths. Practically, the author's conclusions are adverse to the Neuron theory and in favor of the views of Apathy, Bethe, *et al.* The authors and especially Dr. Stewart are to be congratulated. The book will be widely studied.

On Disorders of Assimilation, Digestion, etc. By Sir Lauder Brunton, M.D. London: Macmillan & Co., 1901.

Brunton's present work is composed in the form of lectures, which have been delivered by the author at different times. The book deals with the most varied subjects relating to digestive diseases and constitutional disturbances.

In the section on diabetes mellitus Brunton lays stress upon muscular weakness as one of the earliest symptoms of diabetes. In the treatment of the malady Brunton recommends the use of raw meat, believing that the muscles contain a ferment converting glucose into lactic acid. He is also a great advocate of exercise in this malady. If the patients are unable to exercise he recommends massage. Salicylate of soda and opium he considers as the most important remedies in diabetes.

In discussing the subject of alcohol whether it is a food or not, Brunton is of the opinion that alcohol is a food, although for healthy persons it is not a convenient food.

Alcohol undergoes combustion in the body, but at the same time it tends to lessen the combustion of other things. In healthy people this is, of course, a disadvantage, because it is by the combustion of our food that our strength is maintained. Alcohol, therefore, is for healthy people, a very inconvenient form of food. In fevers the case is different, because then the body is burning away too rapidly, and alcohol has the double advantage of retarding this process, as well as acting itself as a food. In wines, beer and spirits, alcohol is contained, but in each of them it is mixed with other things, which modify its action as a food. On comparing these substances, we see at once that the action of alcohol as a food and as a stimulant are not connected. If we take, for example, a quantity of beer and brandy containing the same amount of alcohol, we will find that the beer is more nourishing, but the brandy is more stimulating.

Brunton appears to be a great adherent of temperance. In the treatment of alcoholism the question arises whether it is advisable to cut off alcoholic liquors entirely from persons who have been accustomed to taking them freely, and who are at length beginning to suffer from the degeneration caused by them. The opinion which Brunton's observations have led him to form on this point is, that if the degenerative processes have not gone far, and there seems reason to believe that the organs, though beginning to suffer, are still fairly healthy, it may be advisable to cut off stimulants altogether. But this is not the case when the degeneration has gone far. When symptoms of dropsy appear, or when the heart is becoming feeble, or the nervous system markedly degenerated, in persons who have been accustomed to take alcohol for a long series of years, the sudden and complete withdrawal of what is to them, not only a stimulus, but is from long habit, to a great extent, a food, is likely to be injurious. If they have indulged in it to a great excess, let it be diminished, but not entirely withdrawn.

As a whole, Brunton's book is very instructive and fluently written. It can be warmly recommended to the profession.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Handbuch der Krankenversorgung und Krankenpflege. By Dr. George Liebe, Paul Jacobsohn and Prof. George Meyer. 8vo, 1078 pages, illustrated. Zweiter Band, Erste Abtheilung. August Hirschwold, Berlin, Germany.

Diagnosis by Means of the Blood. By Robt. L Watkins. 8vo, 388 pages, illustrated. The Physicians' Book Publishing Co., New York. Price, cloth, $5.00.

Transactions of the American Climatological Association, 1901. Vol. XVII. 414 pages.

Hæmolytic Power of Serous Fluids.—H. Strauss and W. Wolff have studied this subject in an extensive manner. In general, there is a relation between the hæmolytic power and the quantity of albumin in serous fluids, but it has not been as yet determined how constant such a relation is and its significance when applied to transudates and exudates. It, nevertheless, appears that the hæmolytic property is closely connected, if not dependent upon the atonic complexity of the albumin molecule. This confirms the views of Ehrlich and Morgenroth.—*Fortschritte der Medicin.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 3, 1902:

	Cases.	Deaths.
Measles	612	22
Diphtheria and croup	313	47
Scarlet fever	420	25
Smallpox	54	14
Varicella	66	..
Tuberculosis	310	133
Typhoid fever	29	10
Cerebro-spinal meningitis	..	4

Surgical Treatment of Hemorrhage from Gastric Ulcer.—Walther Kaupe reviews the literature appertaining to this subject. Gastric ulcers which give rise to serious hemorrhage are usually situated on the lesser curvature in the region of the pylorus. In the operative treatment of this condition various methods have been employed. These are resection of the pylorus, gastroenterostomy, cauterization, excision of the ulcer, tamponade, ligation of the bleeding artery *in situ*, and Witzel's operation. Resection of the pylorus is generally contra-indicated on account of the poor general condition of the patient. Gastroenterostomy has been especially recommended by Küster, Rosenheim, and Doyen when the ulcer is situated on the posterior wall of the stomach. Ulcers situated on the anterior wall are particularly suitable for excision. Here elliptical excision is to be preferred. Cauterization, as a rule, produces only temporary cessation of the hemorrage. Tamponade, as used by Heidenhain has been unsuccessful. Ligation of the bleeding artery *in situ* is very difficult and rarely successful, since the ulcerating tissues are not suitable for ligation and the points of hemorrhage may be multiple and not easily discovered. Recently Witzel has proposed ligation of the superior gastric artery —either the right or left in accordance with the location of the ulcerated and bleeding surface. This method has the great advantage that the operative measures involved are slight and easily borne by debilitated patients. The possibility, however, of secondary gangrene of the stomach, due to restricted blood supply, should be considered. Hofmann, by experimental ligation of this artery in animals, has shown that such a complication is possible. Nevertheless, Witzel's case shows that this method is reliable and practical. A review of the sixteen cases of gastric ulcer which have been operated on by one or another of these methods shows that recovery took place in ten. It is thus apparent that the surgical treatment of hemorrhage from gastric ulcer is a feasible procedure and should be resorted to in all cases which do not respond to internal medication.—*Deutsche Zeitschrift für Chirurgie.*

Exceedingly Rapid, Alternating with Very Slow Respiration, with Pauses Varying from Twenty Seconds to Two Minutes, in a Case of Tuberculous Meningitis, Syphilitic Periarteritis of the Pons and Medulla, and Hysteria.—J. T. Eskridge reports the case of a woman of twenty-nine years, suffering from the above complication of diseases. The variations in respiration were marked, at one period being from ten to fifty per minute, at another two to eleven, with, at times, complete intermissions, lasting from forty seconds to two minutes. Extreme rapidity, 100 to 142 per minute, or extreme slowness, from two to four per minute, occurred only during periods of profound unconsciousness, and never during normal sleep, and variation from the normal respiration occurred more frequently during sleep than when the patient was awake. The hysteria in the case came on only after severe injury to the head. The author concludes that hysteria is often a veil which obscures, or a cloak that hides the symptoms of [illegible] important organs after that [illegible] which it [illegible] when the patient [illegible] of positive evidence of [illegible] of the lungs in the region of the respiratory centers.—*The Journal of Nervous and Mental Disease.*

Excessive Fever Produced by Lesions of the Central Nervous System.—Julius [illegible] reports a case of tertiary syphilis in which there was sudden attack, marked by a severe chill, followed by a high rise in body temperature (42.8° C.—109° F.) and general muscular convulsions. The height of the fever lasted about one hour and then quite rapidly fell, so that on the morning of the following day the temperature reached normal. The intensity of the muscular convulsions gradually subsided with the fall in temperature, so that by the time this had reached normal they had entirely ceased, except in two muscles—the right pectoral and the left gastrocnemius. The convulsions in these two muscles persisted until the following day. They were, however, observed only when the patient was in the horizontal position, and immediately ceased upon his sitting up in bed. The patient, during the attack was entirely unaware of the convulsions, and the only inconvenience complained of was a severe headache. Careful examination failed to reveal any appreciable cause for the attack, and the author regards it as arising from a syphilitic lesion of the central nervous system.—*Medizinische Blätter.*

Etiology of Carcinoma and Auto-implantation of Carcinoma Cells into the Walls of the Stomach and into the Lung.—Gustav Futterer reports a case in which a primary carcinoma, consisting of cylindrical epithelial cells developed from the posterior portions of a goiter, which were subject to friction and pressure, caused by food passing through the œsophagus during deglutition. The carcinoma developed anteriorly, destroyed cartilages, invaded the larynx and trachea in various places; from here tumor particles fell into the air passages and produced colloid, which saturated the lung tissues and filled the alveoli. Then an invasion of the inter- and intra-lobular tissues took place, and a distinct glandular arrangement developed. The primary growth showed no visible production of colloid, but the metastases in the lung represented structures which sometimes showed almost a complete picture of the normal thyroid gland with large masses of colloid. It is certainly interesting to note that the carcinoma cells in their primary growth, where they were found in dense nests, had, to all appearances, lost their physiologic functions, which they resumed to a high degree when transplanted into the lung tissue.—*Medicine.*

Neurasthenia: Its Etiology, Symptomatology and Treatment.—In a general discussion of this topic, A. D. Rockwell says that in his own experience electricity has proven the best remedy. There is, however, a most marked variation in the susceptibility of patients to this therapeutic agent. There are cases in which anything over ten or fifteen milliamperes in any part of the body seems to provoke irritability, while even half this strength applied to the head becomes decidedly disturbing. On the other hand, there are neurasthenics whose very disease seems to render them equal to the endurance of unusual strength of current, which it is found necessary to decrease as improvement progresses. Static electricity is especially valuable in conditions of disturbed circulation resulting in local congestions. Rockwell highly extols the action of static electricity in these conditions. The circulation is equalized, and especially as a tonic and sedative its good effects are not slow in manifesting themselves. In connection with prolonged applications of the high-tension induction current over the kidneys, he has observed in several instances the disappearance from the urine of both albumin and casts.—*International Medical Magazine.*

Some Respiratory Conditions Dependent upon Gout and Obesity.—J. M. Anders inclines to the opinion that the severe paroxysmal dyspnœa seen in obesity is, in many cases, not a true asthma. [illegible] asthma does occur in about 5 per cent. of the cases of obesity. It occurs only in [illegible] persons, and there is an association a gouty state or history in most cases in which true asthma is secondary to obesity. About one-half the cases are curable by overcoming the causative conditions. Gout and obesity are closely associated. Among 196 of the author's cases of corpulence, gout was either in association or had occurred among the antecedents in ninety-seven cases, or 49.5 per cent. There was a history of rheumatism in 34 per cent. of the same group of cases. Gout occurring independently of obesity may also cause asthma. The dry, chronic bronchitis of Laënnec is recognized by most writers as a distinct variety of bronchitis, due to the gouty state. Its means of recognition and its treatment obvious.—*Pennsylvania Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine-Hospital Service, during the week ended May 3, 1902.

SO-CALLED "JOINT DERANGEMENT" FROM MOVABLE BODIES IN JOINTS.*

By JOSEPH D. BRYANT, M.D.,
NEW YORK.

The expression "joint derangement" is a convenient but somewhat antique form of words illustrative of a deficient knowledge of the special causes giving rise to the manifestations begetting it. Formerly the expression was employed synonymously with the supposed presence in joints of movable bodies, defective cartilages, and other unexplainable phenomena not infrequently witnessed in articulations. Later, however, increased knowledge of these facts has taken from the list movable bodies, and to the remaining factors of disturbance one now but infrequently hears "joint derangement" applied.

I will ask your attention only to the "movable bodies" element of the topic.

It may not be amiss to state the fact that the existence in a joint of a movable body was first recognized by Ambrose Parè in 1558, who then described the removal from the knee-joint of such a body by himself. One hundred and thirty-three years later (1691) Pechlin duplicated Paré's experience. In 1726 Monro, and ten years later Simpson, each removed from the knee a movable body, only that of the latter being from the joint of a living subject. During the last one hundred and sixty-nine years extended consideration has been given to the topic by nearly all prominent surgical writers, notably Hunter, Nelaton, Velpeau, Brodie, and Rokitansky, not to omit König, whose modern contentions regarding his belief in their nature have done much, indeed, to foster investigations and hasten etiological conclusions regarding them.

It appears that all freely movable articulations are subject to this infliction; that the knee-joint suffers oftenest, the elbow next in frequency, and that the ankle, shoulder, tempero-maxillary and carpal joints may each comparatively rarely exhibit the infirmity. The number and size of these bodies are variable. Magendie found twenty-five in a knee joint, Haller twenty in a tempero-maxillary, Malgaigne sixty-three in the shoulder-joint. Dr. James Berry reports (1894) a case of a man twenty-two years of age from whose knee 1047 loose bodies were removed. The extremes in number, therefore, are quite as wide apart as can well be imagined. The comparative sizes, too, are quite as marked, varying from that of a mustard seed to dimensions equaling those of the patella and of the astragalus.

The etiology of these bodies is yet a subject of no little contention. Whether or not they are the direct or indirect products of traumatism, or are independent of it, their presence being disclosed as the result of the special attention directed to the injured joint, are matters yet open to differences of opinion. It appears that the structure of these bodies differs, and is variously described by different writers, suggesting at once a difference of origin, of development, and perhaps also of care of observation. Some bodies are characterized as fibrous, others tough and striated, of ligamentous texture, or hard like bone. In the majority of instances they are said to be fibrocartilaginous and, if ancient, possessed of a central bony structure. Their shapes are various, being oval, lenticular, round—in fact, of devious outline, apparently modified in part by their articular environments, as, for instance, in the knee-joint they are usually compressed and wedge-shaped, perhaps raised on one side and hollowed on the other, in some cases resembling in outline the patella, in others angular, with numerous facets.

The etiology of these bodies is, naturally enough, assigned to different causes. They differ not infrequently in all essential characteristics. Hunter regarded their origin as dependent on coagulated blood in the joint cavity, therefore of traumatic inception. Velpeau concurred in this idea. The relations which they occasionally bear to traumatism of the joint, together with the fact that their structure resembles that of formations known to result from the changes in free coagulated blood in other parts of the body, seem to justify this conclusion.

The museum of St. Thomas's Hospital contains several examples of movable bodies in joints, the character of which bodies sustains the preceding ideas of their causation. Movable bodies have been found in joints afflicted with rheumatoid arthritis. In this condition they are found outside the joints and not infrequently gain access to them by means of pressure from without, pushing them against the synovial membrane, causing the latter to finally surround the intruding body. Bony ridges at the cartilaginous margins, especially the knee-joint, may be broken and frequently gain access to the joint-cavity in the manner just described. Brodie said that in the majority of such instances no evidence of previous inflammation had been present, therefore he was inclined to believe that, in some instances at least, these bodies were developed by an independent process characteristic of tumor formation. Practically stated, therefore, the growth had its origin in the synovial structure or outside of this membrane, entering the joint by the pressure process, as already related. Laenunec, Béclard, and Cruveilier concurred in Brodie's belief, and Cruveilier illustrated cases demonstrating their presence in and external to the synovial membrane, attended with free and attached loose bodies in the joint, each covered with synovial membrane, the attached bodies being tethered by slim pedicles, composed of synovial membrane itself.

Bolton, in his excellent article on the topic (*New York Medical Journal*, June 27, 1896), reports seventy-two cases from various sources, which he examined with great care, classifying them according to structure as follows: Cartilage, twenty; Cartilage and bone, nine; articular cartilage, six; fibrocartilage, five; fibrous bodies, five; bone, two;

---

* Read before the Practitioners' Society, April, 1902.

the remaining specified nine comprised four of fibrous inflammatory, two of which were associated with tuberculosis; one each of tubercular tissue, hypertrophied fringes and synovium, two of blood clot in fringe. In sixteen the structure was not stated. Of the seventy-two twenty-three were pedunculated and forty-nine non-pedunculated.

Barth (1898) reports fifty-five cases, all containing cartilage, some partly composed of spongy bone.

I am prompted at this time to describe the important features connected with a recent case of my own, the chief characteristics of which prompted the writing of this paper. Briefly related, the patient's history is as follows: M. W. A., a medical student, aged twenty-five years. Family and personal histories have no bearing on the cause of his infliction. In August, 1901, while riding a bicycle, he was caught between the wheels of two vehicles going in opposite directions, causing him to fall to the pavement, so as to bring the right limb, while in a flexed position, beneath the buttocks. For ten days thereafter the limb was out of use because of pain, tenderness, and swelling of the knee, followed by slow but apparently complete recovery from the effects of the injury. During the following September the patient received a second fall, this time from a street car, striking the pavement in substantially the same manner as in the first instance. This injury was severer than the preceding, but the after effects were less prolonged. Immediately following the disappearance of the primary effects of this accident, crepitation and frequent pain at the outer side of the knee were noticed on movement of the limb, especially during extension from the fixed position as in going up stairs, causing the patient suddenly to stop, because of acute pain and partial immobility of the joint, preventing further extension of the leg. The third and last fall happened November 1, 1901. On this occasion the descent was of the height of two or three steps of an ordinary stairway, the outer side of the right knee striking forcibly against the iron frame of a lecture-room seat. The immediate effects of this injury were severer than those of either of the preceding injuries, but no new manifestations were exhibited. Ten days following the last mishap the patient came under my observation. At this time a movable body of apparently half an inch in diameter could be felt on a line with the articulation, at a point about an inch external to the right border of the patella. Some pain and tenderness attended the manipulation of the object, which latter, though quite freely movable, appeared to be tethered below. A few days later the growth was removed through a vertical incision, an inch in length, made into the joint directly down upon the body. The growth was easily caused to extrude through the opening, being limited only by a thin fibrous pedicle attached apparently below to the semilunar fibrocartilage of that side of the articulation. The cavity of the joint was not examined to note the presence of any associated changes of structure. The incision through the synovial membrane was closed with continuous catgut suture, and that through the integument with interrupted silkworm gut. The saline solution and local anæsthesia were employed. The limb was dressed immovably fixed, and the patient kept in bed for a week. Prompt union without reaction ensued, and was followed by apparently complete recovery. The specimen in question was given at once in charge of Professor E. K. Dunham, who made the following preliminary report:

"The specimen is a piece of spongy bone covered with a thin layer of fibrous tissue. The outer shell of bone is thin and appears continuous except for a few foramina containing blood vessels, and a little adipose tissue. The fibrous covering is more highly cellular near the bone than at the free surface, and a layer of cells contiguous with the bone may be clearly seen in some places. This layer contains a few larger cells which are multinuclear and lie in small excavations in the bone. The interior of the specimen contains plates of bone which divide into branches that join to form a spongy structure.

"The spaces between these bony plates contain fatty marrow supplied with blood vessels in considerable numbers. The surfaces of the bone plates are covered with a layer of flattened cells. The bone is laminated parallel to the surfaces, and contains bone corpuscles regularly and typically arranged. Beneath the periosteal covering there are places where a few laminæ of bone appear to be younger than the rest, indicating bone production by the deeper cells of the periosteum. There are no indications of any recent or past inflammatory process in any part of the specimen, and the tissues are entirely free from cartilage."

In other words, there is but little in the history of this case, and nothing in its intimate structure, to justify the belief that its existence depended alone on the injury that brought it to light. It seems to us quite probable that the injuries and the subsequent phenomena revealed the presence of a body of older beginning than either of the periods of traumatisms that divulged its presence. However, it is not altogether improbable that accelerated development followed the stimulus of the trauma.

It seems proper to say that the failure to expose the joint cavity, with the idea of exploring and noting the appearances in it of any corroborative evidence relating to cause and effect, bearing on the question of the genesis of the body, was rather the result, it is thought, of wise surgical discretion than of indifference or complacency.

The symptoms attendant on the presence in a joint of one or more of these bodies are chiefly dependent on the structure and the use and function of the joint, likewise on whether or not the body be disconnected and freely movable, or be tethered by a long or short pedicle, also upon its size and shape. Those joints in which structural mechanism permit of the widest articular separation and of the most varied movements, and in which functional demands exact the support of burdens under varying degrees of movement, are the articulations that especially suffer from this form of infliction. The knee-joint presents the best theoretical illustration of the preceding varied causal requirements, and, practically, is the most frequently and seriously involved in this respect of any of the joints of the human economy. The shoulder-joint comes next in order, because of the same anatomical reasons, but suffers a lesser degree of infliction, because less frequently burdened in its movements, and, finally, is better protected from external violence.

At the risk of retailing well-known anatomical facts, I will remind you that when the leg is extended the articular surfaces of the knee-joint are firmly opposed and the ligaments uniting the surfaces are then taut, all for the purpose of establishing a firm support. In this position the possibility of lateral or rotary movements is entirely suspended in health. However, if the leg be slowly flexed, the fact is easily demonstrable that just in proportion to the degree of flexion the firmness and extent of the interarticular pressure are lessened, affording opportunity for correspondingly free rotation of the leg. These anatomical truths are of great practical importance in connection with the almost constant presence of backward displacement and external rotation of the head of the tibia in chronic knee-joint disease, when treated irrespective of a proper consideration of their clinical significance. Also, these changes in the relationship of the apposed articular surfaces aid in, and often are, the determining influences which lead to the escape of an offending movable body or defective cartilage from a position causing excruciating pain to the patient. It requires but a thought regarding the comparative relationship of freely movable detached bodies, and the immovable and tethered ones of a joint, to the ever-changing articular structure of one like the knee, to estimate their influences on the immediate use of the joint and the comfort of the patient, during functional activity. The symptoms of movable bodies in joints, especially the knee-joint, are readily recognized by those familiar with the language of this misfortune. An unusually abrupt, unexpected and often excruciating pain at a definite aspect of the joint (usually the inner), with sudden arrest of movement and fixation of the limb at the angle of attack, causing the patient (often suffering from nausea and faintness) to stand still or to lean against a convenient support until the acuteness of the pain lessens, or is entirely relieved by a studied or fortuitous movement of the limb, thus releasing the offending body from the environment causing the distress, is a familiar picture of this infliction.

Usually when the knee is thus attacked the leg is being extended from the flexed position characteristic of walking upon a level surface or ascending stairs. Rotation of the knee before the foot is firmly planted, sometimes causes the pain. This symptomatic picture is varied in the characteristic features in different cases and in repeated attacks, each usually severer than the preceding, followed by a correspondingly increasing traumatic reaction, until finally the joint itself becomes permanently incapacitated.

An extended consideration of the symptoms in their not infrequent and devious manifestations cannot be given now because of the limited time for the purpose. It is not always easy to determine the presence in a joint of a movable body, especially in the absence of the ability to feel with the fingers the object itself. And even when its presence is determined by palpation, the elusiveness of the freely movable ones often temporarily defeats rational efforts of removal. In these cases I am accustomed to advise patients to watch for evidence of its appearance, and when found to maintain quietude of the joint until competent assistance can be had to effect removal. In an instance of this kind, some years ago, I was hastily summoned to come prepared, the patient saying "I have cornered the little cuss at last, and wish it removed at once." Sure enough the patient was right, for I found him restraining, between the thumb and fingers a movable body, which he had again detected, and while maintaining the limb in the same position as when the offending body was noticed, called assistance for final relief. It was removed at once under local anæsthesia. The wound healed promptly and thereafter the patient was relieved from the infliction. In this instance the growth appeared to be fibrous and was attached to the synovial membrane by means of a pedicle, permitting quite free movement of the object. I am disposed to feel that it may not be unwise to pierce, under aseptic care, these bodies with a needle, thus assuring their site later when surgical aid appears. Such cases as these can be safely and satisfactorily removed under proper aseptic precautions. But when the object is free in a joint, and not within the grasp, then often detection and removal are matters requiring the exercise of wise surgical discretion. It is not easy, and sometimes is impossible, to detect in the knee-joint a freely movable body, unless of large size; in fact, large enough to prevent its hiding in not less than one of four marked synovial elongations of the knee-joint, to say nothing of the intercondyloid and interarticular fibrocartilage infoldings of this membrane. The making of a free incision into this joint for the purpose of removal of a supposed movable body should not be indifferently attempted, since the contingencies incident to the act may be of far greater import to the patient in such a case than is surgical inactivity. At all events, exploration should not be made until one is assured of the presence of an offending body by manipulative examination, or until after repeated attacks expose the patient to dangers equal in significance to those of the explorative operation itself.

The results of operative practice under the best regulated forms of aseptic procedure are practically devoid of danger to life and limb. However, the failure to employ a perfected technique invites the severest penalties of the omission which too often the patient alone is compelled to bear.

A FEW CASES OF PENETRATING STAB WOUNDS OF THE ABDOMEN.*

By JOSEPH B. BISSELL, M.D.,
NEW YORK.
VISITING SURGEON TO ST. VINCENT'S AND BELLEVUE HOSPITALS.

This paper makes no pretension other than to relate a few cases which have come under the personal observation of the writer, and it is clinical only in its scope. No cases are quoted of wounds not penetrating the peritoneum. Although the abdominal cavity was entered in every patient, in only two were organs other than omentum or intestine exposed or injured. Once the liver was cut, and in another case the aorta was punctured. The patient with the wounded liver also had an extensive incision into the pericardium and probable laceration of the heart muscles and vessels, which was the primary cause of death:

The following cases are reported according to the date at which they were observed. They were all patients of St. Vincent's Hospital, except the last, who was seen by me at Bellevue Hospital only a few hours before she died:

Case I. J. K., twenty-seven years old, longshoreman. September 20, 1896. Stabbed with an oyster knife; walked into St. Vincent's Hospital about six hours after the accident; condition markedly alcoholic; no symptoms of any injury. Examination showed an incised wound, one and one-half inches in extent, about three-quarters of an inch internal, to and above the right anterior superior spinous process. As the history was indefinite, the wound dry, and there were no indications of penetration into the abdomen or of injury of its contents, the wounded surface and surroundings were antisepticized, dressed with bichloride gauze, and bandaged. The patient was put to bed and treated for his alcoholism, although he had to be prevented by force from leaving the hospital, as he insisted there was nothing the matter with him. At 4.40 A.M., a piece of omentum having been discovered protruding through the wound, the patient was put under ether, the wound was enlarged to release the omentum, which was tightly caught, and the abdominal contents in that region were inspected. A piece of omentum, about the size of a silver quarter, was

*Read before the Hospital Graduates' Club.

ligated and cut off. The peritoneal cut was closed with catgut sutures and a small drain left at the lower end of the abdominal wound which was closed above with catgut. The drain was removed in thirty-six hours. No reaction of any kind followed and there was no pain, no vomiting and no complication. Discharged cured October 3, 1896. This patient was seen two years later and there was no hernia.

Case II.—J. M., forty-seven years old, barber, brought to hospital August 16, 1897, by ambulance; he had a feeble rapid pulse, cold clammy skin and was in shock. He had been stabbed an hour before admission; a wound two inches long was in the right abdominal wall, and a small opening in the peritoneum; no hemorrhage externally or into the wound. The wound was irrigated with saline solution, the peritoneum sutured, and the external wound also closed with sutures. Discharged September 16.

Case III.—L. P., twenty-three years old, male, September 4, 1897. Brought in by ambulance; stabbed with a pocket-knife a short time before admission. There was a small wound in the right side of the abdomen entering the abdominal cavity. No symptoms except the clean cut wound one-half inch long. Antisepticized, sutured, discharged cured September 16, 1897.

Case IV.—B. O., male, thirty-two years old, longshoreman, July 26, 1898, in a desperate fight, was stabbed in several parts of his body. He had one wound in the left shoulder six inches long, another an inch long in the left fifth intercostal space, a two-inch long cut severing the left ninth costal cartilage from its rib, a similar wound on the right side partially severing the ninth costal cartilage of that side, a wound three inches long over the sternum, a wound nine inches long on the outer side of the right thigh, and a punctured wound a little to the left and below the umbilicus, out of which protruded a piece of omentum less than three-quarters of an inch in length. When brought in by the ambulance, a short time after the injuries, he was in deep shock. Pulse 140 and feeble; respiration irregular and down to six per minute. Great pain in breathing, incontinence of urine and fæces, skin cold and wet. The omentum was cleansed and returned and the opening gently packed with gauze. The other wounds were closed with horse-hair sutures. His recovery was uneventful. He was kept on his back in bed for eight weeks. His temperature was never above 99.2°. He left the hospital cured.

Case V.—E. M., twenty-three years old, male, August 30, 1898. Brought in by ambulance for knife wound just penetrating the peritoneum. No other symptoms. The wound was antisepticized and gently packed with gauze. Patient discharged cured September 12, 1898.

Case VI.—F. A., male, twenty-seven years old, October 5, 1898, was stabbed with a pen-knife in the left inguinal region. Brought in by ambulance; slight pain and a little hemorrhage in the wound, which was controlled by gently packing with gauze, wound one-half inch long, nicking peritoneum; left open; ice-coil to the abdomen for forty-eight hours. Discharged cured October 15.

Case VII.—J. C., thirty-five years old, male, November 13, 1898. Stab wound in left iliac region midway along Poupart's ligament and a half inch above it; the wound was half an inch long. There were no symptoms. The usual treatment was followed, and a dressing was applied. Ice cap was kept on the abdomen for five days. Discharged cured.

Case VIII.—J. F., male, thirty years old, January 17, 1900. This patient was brought in by an ambulance in severe shock. He was stabbed in several places with a stiletto. There were three small punctured wounds in the epigastrium and a punctured wound in the sixth left intercostal space three and a half inches from the median line; the abdomen was tympanitic. The patient was conscious, suffering great thirst, with face pale and lips colorless; he was in shock, but the pulse and respiration were good. Exploratory laparotomy in the median line was performed two hours after admission. Three wounds of the liver were found bleeding freely; the cautery was used to arrest hemorrhage. An incision was made over the stab wound of the thorax. It was found to lead into the pericardium. A probe passed several inches to the bottom of the wound could be felt through the diaphragm. The probe moved with each cardiac pulsation. The abdominal incision was closed and sutured. The thorax wound was partially closed, a drain being left in at the lower end of the wound. The patient grew worse, the temperature slowly increasing as well as the pulse and respiration. He died January 22 with temperature 105°, pulse 166, respiration, 42, just before death. Autopsy showed a few peritoneal adhesions. The pericardium was filled with clots, and the lungs were œdematous and much congested.

Case IX.—E. C., female, thirty-six years old, February 2, 1900. Was stabbed with a stiletto. She instantly became dizzy, but did not lose consciousness or fall. The hemorrhage was profuse but had ceased when the ambulance arrived, although her garments and the bed on which she was lying were saturated with blood. On her admission temperature was 99.6°, pulse 102, respiration 24; she had considerable difficulty in breathing, the abdomen was tender and slightly tympanitic. There was a small punctured wound in the epigastrium one and a half inches to the left of the median line, a little below the ribs. A probe, passed under antiseptic precautions, went in easily over four inches, and was apparently free in the abdominal cavity. The abdomen was very thick and fat. Operation was advised but refused, the patient not permitting even the enlargment of the wound. This was antisepticized and dressed as usual and an ice coil was applied. On February 4 the wound had evidently united. Temperature, 101°, pulse 96, respiration 24; February 6, the temperature rose to 103°, pulse 100, respiration, 26. No movement of bowels had occurred since admission; an enema resulted in the passage of a large formed stool. There was a marked point of tenderness in the abdominal wall to the right of the wound, which was increasing. The following day the wound opened and discharged considerable pus. The swelling and tenderness at once subsided. The wound was irrigated for several days until it closed up. The patient was discharged cured February 27, 1900.

Case X.—V. M., male, 24 years old, longshoreman. October 4, 1900. Brought in by ambulance in great shock, said to have been stabbed in the abdomen with a pair of scissors. Examination showed the patient in profound shock, but conscious. Respiration, 30; temperature, 97.6°; pulse, 100, feeble and weak, skin cold and clammy; pupils dilated. Five inches from the median line, a little below the right free border of the ribs, was a clean cut wound half an inch long with the omentum protruding. This was ligated and cut off. The patient's condition forbade further operation, and he died in a few hours. Autopsy showed profuse post-peritoneal hemorrhage from a small punctured wound of the right side of the abdominal aorta about the level of the ninth dorsal vertebra.

CASE XI.—V. A., male, forty-one years old. Frenchman, laborer. Admitted October 22, 1900. The patient was stabbed in six different parts of the body in the evening of the day before admission to the hospital. He went to his room after the stabbing and remained there from 11 P.M. until three the next afternoon when he was brought to hospital by an ambulance. On admission he was very anæmic, but the pulse was fairly full and strong. Temperature, 99.4°. The following wounds were seen: One just below the ensiform cartilage, non-penetrating, in the median line; another just below the umbilicus; one in the left inguinal region, through which came a considerable mass of omental issue; one in the right inguinal region midway between Poupart's ligament and the umbilicus; through this protruded several inches of small intestine, covered with blood, mixed with fecal matter. The patient stated that this condition was present immediately after the injury fourteen or fifteen hours before. There were several irregular punctures in the intestinal wall, through which fecal matter was oozing. There were two other stab wounds in the left thigh. All the external wounds were about an inch long and quite deep. The exposed gut and omentum and the surrounding field were carefully antisepticized, the openings in the gut repaired with Lembert sutures and the omentum ligated and amputated. A median laparotomy was performed and the intestine drawn through the wound from within and carefully examined. No other wounds were found. It was necessary to enlarge the cut through which the intestine protruded, in order to release it. The patient's condition became very critical during the operation, the pulse becoming feeble and so rapid it could not be counted. Therefore the injured gut was brought into the bottom of the laparotomy wound and retained there by a piece of gauze. The wound was left open and dressed with gauze. The bleeding was constant from the right abdominal wound, but was controlled by a suture. This wound afterwards suppurated and made considerable local trouble, but as it was promptly and thoroughly drained it did not infect the peritoneal cavity. The other wounds were sutured, and healed by first intention. The operative wound healed by granulation. No fecal fistula resulted. The patient made an uneventful recovery, and was discharged cured on January 4, 1901. So far as I know, no hernia resulted.

CASE XII.—J. D., forty years old, female. December 28, 1901. The patient was brought into Bellevue Hospital by ambulance about midnight. She had been stabbed with a potato knife. Examination showed one wound over the left temporal region four inches long to the bone; one on the left forearm four inches long; one six or seven inches long on the outer side of the left thigh. All these cuts, except the temporal one, were an inch or more in depth at various points. The bleeding was controlled by pressure and the wounds were sutured. The abdominal wound was over five inches long, beginning a little to the right of and above the umbilicus and extending three or four inches below it, dividing the peritoneum to the full extent of the wound, so that when the patient was brought to the operating table several feet of intestines and omentum were outside of the abdominal wall. There was no wound of the intestine. This was brought out of the peritoneal cavity and its whole length carefully examined. The omentum was also intact. The contents were replaced and the abdominal wound was sewed up with the usual three rows of sutures. The patient was returned from the operating table at half past three in the morning, having been under ether about three hours. On admission her temperature was 99.6°; pulse 108; respiration, 36. At five o'clock the next morning, December 29, the temperature was 100.4°; pulse, 96; respiration, 30. The highest temperature that day was at 6 o'clock in the evening when it was 101.2°, the pulse at the same time remaining 96, and the respirations being 26. She vomited for the first twenty-four hours, apparently from the ether, but the vomiting was not frequent or severe. December 30 there was no vomiting, but the temperature gradually increased until, at 9 in the evening, it was 103.2°, the pulse remaining 120 all day, and the respiration varying from 36 to 42.

On December 31, in the morning, the temperature was 104.8°, the pulse 144, and the respiration 28. The patient had been given calomel in repeated doses, but without effect. A purgative enema was tried, but not retained. At eight o'clock that night the temperature was 104.8°, the pulse 150, and the respiration 42. She vomited twice during the day The vomited matter had no fecal odor. The abdomen was somewhat tympanitic, and not painful, but to the right of the umbilicus was a boggy feeling, which was slightly tender. There was no rigidity of the belly wall. A high enema was again given with no result. The abdominal wound had apparently united, except at the bottom where a small drain had been left in. The patient was still perfectly conscious, but in no pain, with the pulse getting very much worse at 10 o'clock in the evening. Respiration was rapid and not painful. In fact, the patient complained of no pain whatever in the last twenty-four hours; vomiting ceased, but from this time on the pulse grew rapidly worse, œdema of the the lungs began, and she died at 5.20 A.M., January 1, 1902.

Autopsy showed a slight adhesive peritonitis with a rather flat twist of the ascending colon. Beneath this twist was a hard piece of fecal matter, kept there by the muscular band of the cæcum leading to the appendix. The twisted gut was held in this malposition by the tension of the muscular band. The stomach, intestines, and the cæcum were all enormously distended. The transverse colon and the descending portion of the gut were completely collapsed.

In nine of the above cases recovery took place. Of the three patients who died two were, from the nature of their injuries, beyond operative help. The third, the last reported case, might possibly have had a better chance without the exploratory exposure, which seemed necessary at the time, because of the great extent of the external wound.

Two facts strike one at first in considering these cases. The absence of infective peritonitis and the immunity of the omentum and gut in such rather extensive wounds. It is fair to presume that the instruments inflicting the wounds were dirty. The garments which they penetrated were dirty, as well as the skin of the patients' abdomens, and these facts make the freedom from infection the more striking. Patient No. 12, who died, had few symptoms of peritonitis or of sepsis, but died apparently of volvulus and muscular paralysis of the bowel. The other two deaths can hardly be said in any way to have been due to infection. The immunity to infection in such cases is probably due to three causes: (1) The resisting and absorbing power of the serous sac of the peritoneum; (2) The possible cleansing of the instrument as it passed through the fibers of the garments, and (3) The fact that the instruments, as a rule, were polished instrupoints, and did not carry on their surfaces many or very virulent germs. The escape of the intestines from being wounded is explained by their great mobility in the abdominal cavity, and the lubricating, slippery serous membrane which surrounds and protects them. Even in the patient in whom the stiletto had gone clear through the whole depth of the abdominal cavity, from the anterior wall to the aorta at the posterior wall, the intestines had not been wounded. In several of these cases the omentum or intestines or both had been exposed unprotected for hours outside of the cavity, yet these patients made a good recovery. Suppuration occurred only twice. In patient No. 9 a probe was used and probably pushed into and between the layers of the abdominal wall, a procedure (that of using a probe) which is not good surgery. The other case (No. 11) was one in which extensive bleeding was going on in the abdominal wound, and in which, owing to the desperate condition of the patient, I had no time, as in the other cases, to cleanse the wound thoroughly, nor to search for the bleeding vessels, but hurriedly passed sutures through both walls of the wound, thus securing the vessels and stopping the bleeding.

It will be noticed that in none of these cases of stab wounds were the kidneys, bladder, ureter, stomach, or any of the female genital organs involved, or if so they gave no symptoms, and with one exception, that of the aortic wound, there was no bleeding of any importance into the abdominal cavity. The hemorrhage was rather severe in three, but left no lasting effects.

A review of the above results shows that treatment depends much upon the knowledge of the instrument used in the injury, the condition of the patient, and the length of time since the injury took place, and not so much upon the extent of the abdominal wounds or extrusion of the contents; and requires judgment and common sense as well as expert surgical and anatomical knowledge and experience. From a study of these cases one might infer that in wounds made with a small instrument with a point or short cutting edge it is fairly safe to assume that no injury, or a slight one only, has been done to the abdominal contents, and if there are no symptoms pointing to such injury after the first six to eight hours I should be very much inclined to sew up the abdominal wound. It is well known that small injuries of the intestines will take care of themselves by reason of the prolapse of mucous membrane into the puncture or the collapse of the muscular and serous walls together over a wound, thus closing it, and furthermore the very rapid adhesions, which are thrown out in lacerations of the serous membrane, cover and protect the hole. I cannot but believe that if patient No. 12 had not been so theoretically well treated, by having the abdominal contents explored on the table for the period of time necessary for the purpose of examining them carefully, she would have had a better chance of recovery, although the indications were very carefully followed out according to the rules of routine surgical practice.

Regarding hernia as a result of delay in suturing the abdominal wall, I can say but little. In two of these cases I saw the patients several years afterwards, and neither of them had any hernia.

From careful consideration of the above cases, I should draw a few conclusions: A stab wound involving the peritoneal cavity is frequently followed by recovery without operation. In every case the wound, and the field near it, should be thoroughly antisepticized and kept so; an examination should be made with the cleansed fingers, if at all, and only to determine whether the wound penetrates the abdomen and to ascertain if any injury has been done to the contents. If doubt exists about involvement of the organs it is better to bring the divided edge of the peritoneum into the wound, fasten it there, drain and wait. If the abdominal viscera have certainly escaped damage, the wound should be closed by suturing the peritoneum, the muscles, and the skin and fascia in three different layers, catgut being used, or if the wound be long and gapes a catgut running suture may be used for the peritoneum and silkworm in one layer for the skin and muscles. If there be grave doubt and the symptoms point to damage in the peritoneal cavity, the wound must be enlarged and a complete exploration made carefully, or, better still, a median laparotomy may be done exactly as in an examination of tumors of the abdominal cavity. The contents of this cavity should be examined, repaired, if necessary, and returned, and the opening then sutured, as before advised, or, if the damage be too severe, the injured gut or omentum should be brought to the wound and a drain inserted, in order that an exit may be given for a fecal fistula, if that misfortune happen. This last technique is similar to an operation for appendicular abscess or suppurative appendicitis.

If the gut is cut across, it must be united in any one of the usual ways. If the omentum is cut off from its intestine, so much of the intestine as is deprived of its blood supply must be resected. If symptoms of internal hemorrhage are present and increasing the indication is imperative to open the abdomen, find the origin of the bleeding, and control it.

PROPHYLAXIS IN PNEUMONIA

By H. R. TUTHILL, M.D.,
BROOKLYN, N. Y.

The onset of acute lobar pneumonia is generally so sudden and without warning that but little time and opportunity is given to contend with and offset the forces at work. The pronounced chill at the inception of the disease, together with the rapid rise in temperature, accompanied by morning and evening variations, indicates a severe septic invasion not alone of the pulmonary structures, which present the chief physical signs of the disease and are primarily the avenue of infection, but of the whole constitution. It is just as illogical to call pneumonia a local disease, for the reason that the chief structural changes take place within the lungs, as it would be to designate diphtheria as such because the principal lesion is found in the throat. The poisonous products thrown off by the pneumococci are absorbed and circulate in the blood throughout the system, thus producing a general toxæmia, which shows its effect upon the entire organism.

The lungs, however, being the primary seat of infection, have to stand the brunt of the attack as the characteristic phenomena indicate. The respiratory and circulatory disturbance points to a toxic influence at work on the nerve centers governing those functions. It has been found that there is generally present a leucocytosis in pneumonia, and observers have stated that the greater the number of leucocytes the better are the chances of recovery; whereas in fatal cases a comparatively small number of leucocytes was the rule. The leucocytes are found in large quantities in the blood and also in the alveoli, together with red blood cells, epithelial cells, and fibrin. As the leucocytes are said to be capable of transporting foreign substances, poisons, etc., in the blood, it might be reasonable to suppose that the organism attempts to throw off the toxins by means of the leucocytes, which take up the poisonous material and find their way, by emigration, from the pulmonary capillaries into the alveoli, where they may be gotten rid of with the exudation by expectoration. The exudation into the alveoli seems to be nature's attempt at elimination. The spleen is usually enlarged in pneumonia, and, as this organ is thought to be the chief source of origin of the leucocytes, it is not unreasonable to conclude that its temporary hypertrophy is due to increased activity in the production of these corpuscles, which seem at this time to be in great demand by the economy.

The phenomena presented by acute lobar pneumonia give one the impression of two great forces engaged in battle with one another. With the occurrence of the crisis it appears as though one force had succeeded in subduing and overthrowing the power of the other, such as one might imagine would occur on an ordinary battle-field. If the antitoxic influence can be mustered by the economy in sufficient strength to counteract or destroy the power of the bacilli and their toxins, rendering them inert, it can well be seen how the toxæmic symptoms would suddenly subside. How otherwise can it be explained that cases of pneumonia, with practically no medication, go through all the toxæmic symptoms and then suddenly end by crisis and recover.

In fatal cases it is most probable that the respiratory and circulatory centers have become paralyzed by the action of the poisons in the blood. The dilirium and other mental and nervous phenomena, commonly present in pneumonia, all indicate a severe toxic influence at work on the brain and nerve centers. That the embarrassed respiration and labored pulse is not caused by obstruction in the lung tissue is well known from the fact that when the temperature has dropped to normal by crisis the respiratory and circulatory disturbance subsides, although the alveoli are still filled with the exudative products.

In view of the fact that fibrin is found in such large quantity in the blood, and the alveoli in pneumonia, and the belief that the leucocytes are an important factor in its production one might be led to suppose that the latter play a chief rôle in the attempt to repel bacterial invasion. Moreover, they rapidly diminish in number after the crisis. The condition after death, when the air spaces are found filled with pus and degenerated epithelial cells, shows what purulent influences have been at work. Then it appears to be a battle royal between the resources of the patient on the one hand and the poison-producing power of the bacilli on the other. When lobar pneumonia has gone on to the second stage and exudation has become well established, there is probably nothing that will prevent it from continuing on through its course. Before consolidation has begun or become firmly established, however, there is much that can be at least attempted. Some writers claim that it is possible to abort pneumonia, while others state that no drug or method of treatment known at the present time is successful. Probably there is no method which would prove to be infallible. The symptoms set in usually so abruptly and with so short an interval between the congestive stage and exudative stage that but little time is allowed in which to accomplish anything. In those cases, however, where the congestive stage lasts for some hours or days more opportunity is given to act.

It is difficult to understand what benefit such drugs as aconite and veratrum viridi can exert in the first stage of acute lobar pneumonia. They may succeed in diminishing the number of pulsations and the strength of the pulse by depressing the heart. They may also temporarily reduce the temperature. But the rise in temperature and the rapidity of the pulse are merely symptoms of infection. By weakening the force of the circulation the congestion in the lungs must be increased rather than diminished, for the blood passing more sluglishly through the capillaries would allow more or less stasis to occur, and, therefore, simply aggravate matters, while vigorous pulsations would send the blood more rapidly through the lungs and on to other parts of the body. Also by depressing the heart these drugs create a condition that occurs only too soon in pneumonia, and one which should be studiously avoided. What is the use of dallying with mere symptoms when we know that they are but signs of a deep-seated infection? The rapid and angry pulse and increased number of respirations simply indicate irritation of those respective nerve centers by bacterial poisons. The rise in temperature signifies increased chemical activity going on in the body, caused either by the action of the bacteria or the effort of the economy to destroy them. It hardly seems possible that aconite, veratrum viridi, or any other mere cardiac depressant ever shortened or benefited lobar pneumonia.

Knowing the microbic origin of the disease, the most rational mode of treatment undoubtedly consists in the administration of internal antiseptic agents, which, upon being brought in contact with the bacilli through the medium of the blood, may be enabled either to destroy them or at least to embarrass their growth and development and check the influence of their poisons. In this way we may be able to assist nature in her fight with the intruder. At any rate it is more satisfactory to feel that we are making some effort along rational lines rather than treating the patient entirely symptomatically or expectantly and leaving the whole affair to nature.

Several drugs have recently been advocated as prophylactic agents in pneumonia, by means of which the disease is said to have been either shortened, prevented, or favorably influenced, such as creasote, and the carbonate of creasote. The writer has had very good results with salol given in the first stage of pneumonia. In several instances it certainly cut short the disease and prevented consolidation. As solol is not broken up into its constituent parts before reaching the intestine there is no danger of its deranging the stomach, and it has no injurious effect upon the action of the heart unless given in poisonous doses.

Sternberg, in his "Manual of Bacteriology," says that in his experiments concerning the action of various agents on the pneumococcus he found that a 1 per cent. solution of carbolic acid destroyed the vitality of the germs in two hours, while a solution of 1 to 500 restrained development. A solution of salicylic acid, of the strength of 1 to 400, prevented development.

These facts show that the drugs named have a direct specific action when brought in contact with the bacillus, and while we may not be able to give them internally in such proportions or dilutions, it likewise does not seem to be necessary in order to obtain an inhibitory effect; for nature at the same time is undoubtedly making efforts in the same direction.

Salol was given at the earliest possible opportunity when the symptoms pointed to a commencing or threatening lobar pneumonia. Ten grains every two hours in adults seemed to work well, widening the intervals as the symptoms subsided. Among other cases were the following:

Mr. H., aged forty-five years, a conductor on the elevated railroad. He had a severe chill in the early part of the afternoon after having been exposed to falling snow and cold on the platform of his car. When seen a few hours later his temperature was 104°, pulse 120, respiration 28. He complained of pain in the right side of his chest and of difficulty in breathing, and had a harassing cough, the expectoration being scanty and tenacious, slightly streaked with blood. A deep red flush showed on his cheeks and he was very nervous and excited. He had had pneumonia twice before and stood in perfect dread of it. On auscultation crepitant râles were heard over the middle portion of the right lung. He was ordered a saline purge, counter-irritation to the chest by means of a mustard plaster, and salol gr. 10 every two hours. At noon the next day his temperature was 100°, pulse 90, respiration 24. The day following his temperature was normal and continued so; pulse 80, respiration 20. He felt practically well, with the exception of a slight cough, which soon disappeared.

Annie H., aged twelve years, had a severe chill followed by cough and fever. When seen there was copious expectoration of blood-streaked sputum. Her temperature was 102°, pulse 110, respiration 30. Crepitation over lower lobe of right lung. She took salol gr. 5 every two hours for the first few doses, then every three hours. She also took a saline purge and an expectorant cough mixture. The symptoms rapidly subsided, and in thirty-six hours the temperature and respiration were normal, pulse 84. Blood still slightly discolored the sputum for two days and then ceased.

Mr. C. had a chill early in the morning, accompanied by nausea and vomiting. When seen about 10.30 A.M., his temperature was 103.5°, respiration 33, pulse 100, pain on left side of chest, crepitant râles over apex of left lung; cough and expectoration. He was given salol gr. 10 every two hours. That evening his temperature was down to 101.4°, pulse 90, respiration, 26. The following evening his temperature was 98.8° and the other symptoms had subsided.

A lady aged fifty-two years had a chill, followed by soreness in the chest, cough and expectoration of frothy mucus, also dull pain in back of head. Temperature 101.6°, respiration, 24, pulse 90. Crepitation over left lung. She was given salol gr. 10 every two hours, and a saline purge. Temperature came down to normal in a few hours and other symptoms ceased. A slight cough lasted for about three days.

83 Monroe Street.

Heart Disease in Children—The Syphilitic Factor.—William MacKenzie says that pericarditis and not endocarditis is the common lesion met with in the so-called pure rheumatic hearts. Indeed, in most of the cases that have died with heart failure thickening and adhesions of the pericardium, and a healthy endocardium has been the rule. In the syphilitic patients the endocardium, and in no case the pericardium, was affected. In any child showing symptoms of early and rapid heart failure after the initial endocardial attack, a suspicion of lues must be entertained. Early dropsy is characteristic of the failure of the luetic cases with endocarditis, should the patients live long enough, and is, probably, largely dependent on syphilitic arteritis. Dropsy is not seen in the early failures of pure rheumatic cases. It is seen in the later failures as the result probably of a degenerative arteritis from malnutrition, is irresponsive to treatment, and too often ushers in the end.—*International Medical Journal of Australasia.*

THE GENERAL COMPLICATIONS AND SEQUELÆ OF MEASLES.

By [illegible], M.D.,

[illegible]

Uncomplicated measles very rarely and exceptionally kills the patient. Death ensues in consequence of the gravity of the complications from which the measles patients have suffered, and all the general complications and sequelæ are fortunately by no means grave and fatal all the time, and at all places. The experience of different individual observers in different countries, at different times, differ and vary within wide limits. Measles epidemics have varied in their mortality rates from less than 1 per cent. to over 20 per cent. Taking all epidemics and all observers into account, we may say that not an organ nor a tissue of the body escapes the disease processes that complete the composite clinical picture of measles. But the tissues most eminently, frequently, and variously affected by measles, when complications are considered, are the mucous membranes and the organs into the composition of which they enter as integral parts.

Mouth Affections.—During the twenty years that I have been in private practice in New York, stomatitis had been the only mouth complication that I have seen. It has not seemed to me an aphthous affection, but an exaggerated condition of what usually takes place. I have seen aphthæ and measles associated, and when so, then the aphthæ were incidental and not essential or integral phenomena. Gangrene affecting the gums, cheeks, fauces, tonsils, and tongue is usually reported from hospitals, and occurs in cachectic children, who usually die. Diphtheria occurring in these parts is also reported. With the nasal and laryngeal complications severe congestion during the early stages of measles occur, but rarely nasal hemorrhages, and when this does occur it is very rarely of any serious significance. One of my cases, a girl three years old, had severe nasal hemorrhages during the end of the first week of measles and died, but in her case there were besides bronchitis and bronchopneumonia. Diphtheria of the nose, as in the mouth, is rare, and diphtheria, says Jürgensen, does not show a great affinity for measles, although Henoch, basing his assertion on what he saw at the Berlin Charité, says diphtheria shows a greater tendency to attack measles cases than the reverse. An observer's good or bad luck in these cases gives color to his opinions concerning the serious nature of these complications. Twenty years ago Henoch was pessimistic regarding them. He saw eighteen cases of diphtheria affecting the upper respiratory tract among 204 cases of measles, and fourteen of the patients died, death being due to extension of the pseudomembrane into the larynx and bronchi. Embden, on the other hand, in 461 cases of measles at Heidelberg, saw two cases of pharyngeal diphtheria, and only one of the patients died, the diphtheria extending into the larynx. Embden also reported six cases of laryngeal diphtheria, complicating measles, and all fatal. Rauchfuss in 1176 cases of measles saw diphtheria of the pharynx eleven times, pharynx and larynx combined nine times, and of the larynx alone thirteen times. The complicating diphtheria is usually painted in dark red colors; and it is said that when combined with measles its development and progress are more insidious than when diphtheria occurs alone. In private practice the combination is rare. I have on record two cases of combined nasopharyngeal and tonsillar diphtheria. One in a boy, the other in a girl, and both in the sixth year of life. Both recovered. The boy was given 1,000 units of antitoxin. The girl's case dates back to preantitoxin days. In the boy's case palatal paresis followed, but ultimate recovery was good. In both cases there had been croupal cough. When diphtheria can be excluded croupal symptoms, even when severe, need not dishearten us. Henoch's bad hospital experience taught him to be anxious, and he impressed his anxiety on others. Eustace Smith teaches, what many of us have often experienced, that during the early stages of measles the croupal cough and laryngismus may be out of all proportion to the catarrhal symptoms. This same complication may occur during the later or desquamative stage. Jürgensen tells us he has seen cases so severe as to keep the surgeons in readiness to perform tracheotomy, and yet the anxiety of bystanders, and the need of surgical interference was cleared away by means of a hot full bath.

Slight erosions of the mucous membrane of the posterior laryngeal wall have been reported by Gerhardt and Lovi, but, from a clinical point of view, they are of little pressing importance. Glottic and subglottic œdema are also reported, but this occurrence is rare. Ulcerations of the nasal and laryngeal cartilages are also rare occurrences, taking place during the later stages of the (measles) disease.

The Lungs.—The complications affecting the lungs are the most frequent, and are of most importance to the general practitioner, namely, the acute bronchitis of various grades of gravity, and catarrhal or bronchial pneumonia. In my experience suffocative attacks simulating asthma affect only few children during the early stage of measles. These attacks are said to be due to severe congestion of the mucous membrane of the bronchials. They occur in rickety children of a neurotic temperament or constitution.

More than half a century ago Gregory opined that over 90 per cent. of measles fatalities were due to pneumonia, and Jürgensen judiciously remarked that, on a basis of calculation not too extensive nor beyond dispute, the pneumonias complicating measles may be placed at about 33⅓ per cent.

At Keil (Jürgensen), in 1860, during an epidemic of measles, the chief cause of death was a peculiar state of the lungs; in parts collapse and specked with foci of purulent infiltration. Besides an intense croupal catarrh extended into the minute bronchial tubes. Taken all in all, the bronchopneumonias complicating measles do not vary from those occurring under other considerations. They may occur during any of the different stages of measles. Croupous pneumonia also complicates measles, but is rather an accidental than an integral or essential or sequential complication. Fibrous pneumonia is one of the rarer sequellæ, and so is tuberculosis. None of my measles patients, so far as I know, have developed tuberculosis as a result of measles.

Jürgensen, speaking from the view-point of a large and varied experience, says he has not often seen tuberculosis develop after measles, and he deemed it rather an accidental than an essential or integral complication of measles. Other observers, however, have believed or imagined measles to be a potent promoter of conditions which favor the development of all kinds of tuberculous diseases, military tuberculosis, joint tuberculosis, and pulmonary tuberculosis.

The complications affecting the digestive tract vary in severity and importance, and are not constant phenomena in all cases. Some have reported slight jaundice. A catarrhal condition of the mucous membrane of the alimentary canal may be present. Thomas reports a swollen condition of Peyer's patches which never develop into ulceration, and which seem to disappear as cutaneous desquamation advances. Colitis of all grades are reported, associated with diarrhœa, even ulcerative hemorrhages. When diarrhœa lasts for any considerable length of time after convalescence should have been established, Jürgensen is of the opinion that in such cases other special disease germs are at work. The kidneys rarely suffer. And little importance need be attached to small quantities of albumin found in the urine. Atkins, quoting Parkes, writes that during an epidemic of measles at Leith, in 1854, recoveries from measles were most speedy when the albuminuria was greatest.

The vulvæ are on very rare occasions attacked with gangrene, and also very rarely by diphtheria. Dawson Williams teaches, from hospital experience, that "inflammation of the vulva with mucopurulent discharge is a frequent complication of measles in strumous children." This complication in private practice is rare in the city.

The serous membranes are rarely affected during measles, or in consequence thereof. Pleurisy is a very rare complication, and, as a rule, secondary to, and located usually over the seat of bronchopneumonia. Endocarditis is rare, and pericarditis rarer still. The heart muscle itself is not affected by the measles virus, says Jürgensen, but, during an epidemic at Wurzburg, it was believed that this did occur—that is, hypertrophous dilatation."

In Pepper's "System of Medicine" Hardaway reports that Chadbourne found heart-clot, and subsequent pulmonary œdema, the cause of a number of deaths, where pneumonia processes had not existed in the course of measles. Chadbourne found these heart-clots of a gelatinous character, extending into the pulmonary arteries, and Keating also found heart-clots in measles cases, the formation of which he attributed to the work of Micrococci which were seen in the blood, and white blood-corpuscles.

Some observers teach that measles have a causative influence in giving rise to synovial and rheumatic joint diseases. Dawson Williams again tells us, what very few of us here in New York have observed, that a subacute peritonitis occasionally occurs as a late complication of measles, and is found chiefly in girls. The amount of fluid may be sufficient to considerably distend the abdomen; but, fortunately, this fluid is absorbed in the course of a few weeks.

Toward the end of an attack of measles the lymph glands in different parts of the body may become inflamed and enlarged, and the bronchial glands may become caseous or tuberculous. The late John T. Metcalfe long ago reported an interesting case, in which the deep lymphatics of the neck became so enlarged as to compress the deep jugular vein, and this caused death. But serious glandular diseases directly due to measles are extremely rare occurrences, even when the adjacent mucous membrane has been made the seat of more or less severe disorder. According to Biermer and Williams, severe and obstinate attacks of bronchial asthma, after measles, may be due to enlarged bronchial glands pressing on the vagus nerve.

Other glands, like the spleen and liver, may become temporarily enlarged, but they give rise to no symptoms. Rotch, however, tells us that the thyroid glands may become acutely affected in the course of measles, and to the extent of making breathing difficult; but the difficulty passes away in a few days. [illegible] says that [illegible] adhesions to [illegible] and partial destruction of the glands.

The nervous system: chorea and other nervous [illegible] phenomena are [illegible], but the more serious complications and sequelæ are extremely rare. Convulsions at the onset of measles [illegible] when they occur at all are as a rule end favorably.

I saw convulsions of a serious character [illegible] years [illegible] in a strong, temperate and otherwise healthy man, twenty-eight years of age. This man had [illegible] only during the course of measles. During later stages of measles convulsions may precede the development of other complications, such as bronchopneumonia.

Heberden mentions a case of functional nervous disturbance which is unique but interesting: "The patient was seized with a spitting on the day of the eruption which continued to tease him for forty-eight hours without suffering him to rest at all during the day, or sleep at night; the cough in the meantime almost ceased, and all the other symptoms were as mild as in a favorable sort of measles."

Tremors and great nervous depressions developing in the course of measles accompany and are due to other organic complications of some kind, as pneumonia and its secondary manifestations. This depression may end in coma. Such a case is recorded by Heberden; this child became comatose on the third day of the eruption and died the next day. We are sometimes taught that complications coming on during the eruptive stage of measles are not usually significant or dangerous. Whatever may be said, each case, along with its complications, is a problem in itself. When pneumonia and bronchitis are complications, oxygenation becomes deficient and carbonic acid toxæmia depresses nerve centers of various kinds, so that œdema of the brain ventricles may develop. (Jurgensen.) An attack of measles may end in mental torpor and even in a state of mind simulating dementia. Chorea and tetany, hemiplegia (Osler, Gowers), muscular atrophy, ascending myelitis and disseminated myelitis have, from time to time, been attributed to an attack of measles, not by the general practitioner, but by specialists, who seem satisfied with the etiological factor, but which to some others seem rather far-fetched.

Concerning the blood changes and its complications, which measles engender, very little seems to be positively and definitely known.

Cabot teaches that in mild cases no changes occur at all. Comparatively few red blood cells are lost. During the eruptive stages there is usually no leucocytosis—in this respect differing from scarlet fever, diphtheria and roseola. In toxic attacks of measles the blood is wanting in coagulability, and the walls of the blood vessels are diminished during the fever. In complicated cases it is said that the fibrin becomes slightly increased, but this assertion does not tally with what other writers found, a lack of coagulating power of the blood, which caused George B. Wood about fifty or more years ago to surmise in a cursory way that measles is a febrile rather than an inflammatory disease. In the first edition of his book on children's diseases, Hennoch mentions the case of a child that felt well and was uncomplaining, although its measles was associated with purpura and bloody stools. Cocci have been found in the blood of complicated measles, but patient investigation has not yet discovered an undisputed specific microbe.

EYE COMPLICATIONS OF MEASLES AND THEIR TREATMENT.

By H. N. [illegible], M.D.,

ASSISTANT [illegible] MANHATTAN EYE [illegible]

In common with other diseases, [illegible] and noteworthy that all the conjunctivæ [illegible] inflammation during the course of measles.

The following may be mentioned: Conjunctivitis, simple or mucopurulent, further and additional complications, keratitis, blepharitis, blepharospasm, [illegible], and [illegible].

Simple conjunctivitis is a constant accompaniment of measles and shows itself before the eruption; there is a redness of the conjunctiva due to congestion, a rather copious lachrymal flow, and some photophobia; accompanying this there is sneezing, more or less violent. With ordinary care and cleanliness this usually gets well in a week or two: warm water cleansing, bathing the conjunctivæ with boric acid solution and using a bland oil or vaseline between the lids to keep them from gluing together; not infrequently parents have the notion on account of this conjunctivitis that a dark room is necessary, and so exclude the light by closing the shutters and pulling down the shades; there is no need of this, while a subdued light may be grateful to the little patient; it is never necessary to altogether exclude light and air, so needful to both ill and well. In this mild and so common form of conjunctivitis simple remedies are all that is needed.

There may, however, be a more active inflammatory process, a mucopurulent conjunctivitis; here the reaction is more pronounced; more redness and injection of the conjunctiva, the blood vessels of the palpebra and ocular conjunctiva more injected; a more copious discharge, at first watery, changing to a mucous or mucopurulent character; there may also be some redness and swelling of the lids and pain with photophobia; here more active treatment will be required, frequent cleansing with warm water, bathing with boric acid or borax solutions, and where there is swelling of the lids ice cloths for a half hour three or four times a day; also a bland oil or white vaseline between the lids; this serves a double purpose, that of a grateful lubricant, also to keep the lids from sticking together; in these acute cases it is very rarely necessary to use an astringent; most acute diseases have a tendency of their own to get well. To use an astringent would be adding fuel to the flame. Silver, copper, zinc, or even the mild alum solution or stick are not indicated during the acute activity of this conjunctivitis, nor is atropine necessary unless the cornea is endangered, or has become the seat of inflammation. A picture at times presented is the following: as the result of a rather severe discharge, of a mucopurulent nature, and from lack of cleanliness and ordinary care, crusts of dried secretion form on the lids and cilia; the lids are glued together, the child being unable to open the lids; so it is not uncommon to hear it reported that the child was blind for so and so many days; here, by soaking the dried secretion with warm water and cleansing and vaseline, one may get the credit of restoring sight to a blind patient.

Blepharitis is only to be mentioned in passing. While not an immediate complication, it is at times a persistent sequela of measles; there remains a redness of the edge of the lids, which if continued will result in thickening; there is also a dry, scaly exudate; all this gives the eye a peculiar characteristic appearance. Treatment: hot water applications to reduce the congestion, a mildly stimulating ointment, preferably the yellow oxide of mercury, 2 grs. to 1 oz., applied once or twice a day. These cases are generally benefited by internal tonic treatment; cod liver oil, the hypophosphites, etc. Particular attention should also be given to the hygiene of the patient; personal cleanliness, proper feeding, and proper sleeping accommodations.

Blepharospasm is also to be mentioned in this connection, either accompanying or resulting from the acute conjunctivitis or that form of keratitis observed with measles. This blepharospasm, a spasmodic contraction of the orbicularis, may be more or less severe and persistent, and is usually a rather troublesome condition. The relief for this condition consists in treating the cause, whether in the conjunctiva or in the cornea; also the forcible separation of the lids, divulgence similar to other sphincters; either with the fingers, or the lid retractors, being careful in either instance to have no pressure made on the globe; internal treatment in these cases is also of great importance.

Hordeolum-Sty.—Just a word of this. As the result of the inflamed conjunctiva, one or several of the glands of the lids also take on an inflamed state; this is characterized by a local swelling, gradually extending, followed by a pointing of the resulting abscess; here, when pus has formed, hot water applications will usually open the abscess and allow the discharge of the pus; where this does not happen, the evacuaton of the pus may be hastened by wrapping some cotton about the two blades of an ordinary dressing forceps; catching the sty between these, forcibly squeezing it, will empty the inflamed sac, and so bring about recovery; this, though somewhat painful, is a speedy method of relieving the condition.

We now come to the more serious and dangerous complication to be considered in this paper, keratitis, either of its own initiative, or as a result of extension of the conjunctivitis, or of its long-continued course, cornea involvement results; here we have a more serious disease to handle, one that may lead to a permanent crippling or disfigurement of the cornea. Though, fortunately, rare, it is met with in a certain number of cases: in children of a constitution weak by nature or run down from some previous disease; in children with poor hygienic surroundings, improperly or under fed; in children of parents of the very poor, and in those ignorant of the laws of health and hygiene. Keratitis may be slight and the patient get well quickly; or the recovery protracted, the deeper layers of the cornea attacked, destruction of cornea tissue resulting in a corneal ulcer.

The before-mentioned symptoms of conjunctivitis being present, it will be noticed that the photophobia and pain continue; the child avoids the light and will bury its face in the pillow; there is lachrymation perhaps; some mucopurulent discharge; the photophobia is at times an aggravated and aggravating symptom; the child will resist the separation of the lids to allow an inspection of the cornea. Right here a word of caution is, perhaps, admissible. In attempting an inspection of the cornea, be sure to make no pressure on the globe of the eye; it may be that a corneal ulcer is on the point of breaking through; a thin layer of cornea tissue, perhaps Descimet's membrane, the most posterior layer, may only just keep the aqueous humor from evacuating; it will be no pleasure, on a successful separation of the lids, to have the aqueous fluid bursting through the cornea, spurting up, fountain-like, perhaps into the face of the observer; so making no pressure on the globe, previously drying the skin of the patient with cotton, and putting the thumb of one hand over the lower eye-lid, with the ball of the thumb resting on the bony part of the orbit below, we make the pressure on the bone pull the lower lid down; and at the same time place two fingers of the other hand on the upper lid, resting the fingers on the rim of the orbit above, and pull the lid up; at times it will be necessary to catch the margin of the upper lid with the points of the fingers. This manœuvre is best accomplished with the child's head resting on a towel between the knees of the observer. This procedure will usually expose the cornea for examination. The lid retractor is not to be recommended, except in the hands of those accustomed to its use.

But to return to our subject. The cornea being involved, the photophobia and blepharospasm continue; photophobia, fear of light, being a rather constant symptom of keratitis. On separating the lids, a spot of infiltration of the cornea will be seen; this will appear of an opaque character, more or less extensive, and may show itself at any part of the cornea, there being no one point of the cornea more liable to involvement than another; under treatment this may resolve and the patient get well; or the infiltration continue, the cornea break down and cornea ulcer result; the pupil will be contracted, pain complained of, lachrymation is present. When the ulcerative process is severe in turn, the several layers of the cornea become involved and destroyed, and, finally, only the posterior lining membrane exist; this from the intraocular pressure may be pushed through the necrosed cornea, and present as a shining watery vesicle; may burst and the anterior chamber be evacuated; the iris is now well forward on the cornea and danger of adhesion is great (anterior synechia); often this synechia is permanent.

As an ulcerative condition anywhere always involves destruction of tissue, so here; in the healing process that part of the cornea destroyed by the ulcer is replaced by cicatricial tissue, which is always of a white, opaque color and is permanent, thus causing a disfigurement as well as a crippling of the organ. In the treatment of cornea inflammations ice is not admissible, because of the danger of cutting off the circulation; but rather hot water should be used; taking a small towel or napkin, or pledget of cotton, dip it in very hot water, as hot as the hand will stand, apply it to the closed eye lids for a period of ten or fifteen minutes every two or three hours.

Atropine is indicated here. The writer's rule is to instill a two-grain solution into the eye frequently (every hour) until the iris is well dilated, care, of course, being taken to avoid poisoning; after that use the atropine often enough to keep the pupil dilated, say two or three times a day; the reason for this being to get the iris away from the anterior capsule of the lens, to avoid synechia posterior; also; if perforation of the cornea should result, the iris is in the most favorable position; also atropine in these cases has a local soothing effect. Boric acid cleansing for the discharge and white vaseline between the lids can be used as needed.

It will not be necessary to put the little patient into a dark room; air and light are excellent tonics; if the photophobia is a prominent symptom the light may be subdued. Much depends on constitutional treatment in the management of these cases; proper feeding of the patient comes first; tea and coffee and sweets are to be absolutely interdicted. Plain, simple, nutritious diet, mostly milk, to be ordered; baths, both sponge and tub; attention to cleanliness and personal hygiene; bowels to be kept open.

Tonics Internally.—In the writer's experience cod liver oil is one of the best for children, and most children take it kindly. The syrup of the iodide of iron may also be given to good advantage. Special attention must, however, be given to the feeding of the patient, as on this may often depend the recovery of an eye, the seat of ulcerative keratitis, a complication so frequent in measles. To recapitulate those considered in this paper: (1) Conjunctivitis, simple or mucopurulent, blennorrhœa; (2) blepharospasm; (3) blepharitis; (4) hordeolum; and (5) keratitis, superficial, diffuse and ulcerative.

CEREBRAL ABSCESS.*

By C. E. RUTH, M.D.,
KEOKUK, IA.

PROFESSOR OF ANATOMY AND CEREBRAL SURGERY, KEOKUK MEDICAL COLLEGE, COLLEGE OF PHYSICIANS AND SURGEONS.

CASE I.—In January, 1889, I was called to see M. B. C., aged twenty-four years, Muscatine, Ia., who for six years had had suppurative inflammation of the right middle ear. Seven days previously the discharge from the ear had suddenly ceased and cerebral symptoms rapidly developed and grew serious, pulse 40, respirations 12 per minute, temperature normal. I diagnosed cerebral abscess, and advised immediate operation. I first saw the patient at 11 P.M. It was decided to await the arrival of Dr. Morridge, the family physician, on the 7 A.M. train. The operation was then postponed, as slight indications for improvement were noted. The case showed slight variation in its course, with a practically normal temperature all the time, for seven days, when death occurred. No post mortem was obtained. That death was due to cerebral abscess, I have not the slightest doubt.

CASE II.—January 20, 1901, I was first called, by Dr. R. L. Cashburn, to see Miss Mary C., of Carthage, Ill., aged twenty-five years. For five years she had had suppurative inflammation of the left middle ear. During this time she has had slight occasional attacks of headache and earache, relieved by purulent discharge. January 8, 1900, she consulted Dr. C. for earache and pain in left side of head. January 14 pain was worse, and Dr. C. was called to the house. She was seen by him daily thereafter. Temperature and pulse practically normal. Some slight mental hebetude at times. When first seen by me, January 20, 1900, pulse was 72, temperature 99°. No pain, mind clear, pupils equal and readily responded to light. No motor disturbance. Refused operation for lack of evidence of grave lesion, though Dr. C. insisted that she had, a few hours previously, presented symptoms of cerebral compression which he believed due to cerebral abscess. Fetid pus in small quantities exuded from the middle ear through perforation in the drum membrane. The meatus was so badly swollen as to interfere with free drainage. At 7 P.M. January 21 the pulse was 66, temperature 98°. There was spasm of the muscles of expression, and the patient had been comatose for fourteen hours. Operation was immediately performed. I trephined one inch above and one-half inch behind the meatus auditorius externus. The dura was found bulging, without pulsation. The abscess was opened at a depth of one-fourth inch and discharged about three ounces of fetid pus. I inserted three-inch drainage tubes, which became choked with cerebral débris and were removed in a couple of days. Cerebral hernia was marked, and much cerebral tissue was lost. Consciousness was soon regained, and retained until February 17, 1900, when the patient suddenly became unconscious, with twitching of the muscles of expression. She was comatose for sixteen hours and evidently moribund. I immediately opened up and cleared out all the mastoid cells, opening into the attic, and to the tip of the mastoid process, then evacuated an abscess containing two ounces of pus from below and in front of the old abscess cavity, and drained as before. Improvement was now steady, the wound gradually closed, and the patient seemed well, save for a discharge from the ear and irritation in the auditory canal. The cicatrix was firm without any tendency whatever to bulging. During May, 1900, while I was away from home, Dr. Maxwell did some minor operation for relief of irritation in the auditory canal. July 27, 1900, I removed two sequestra of necrosed petrous bone from the auditory canal. One was the size of a grain of wheat, the other one-fourth by one-half inch, and very irregular. This large mass was removed without anæsthesia. The patient made rapid and complete recovery, and she remains well at this writing, December 4, 1901. She has all her faculties unimpaired, save hearing, which is entirely lost on left side. Motion, coordination, sensation, as well as memory, as good as before, according to report of Dr. C. and relatives of the patient.

CASE III.—O. P., aged twenty-six years, of Elvaston, Ill., seen August 30, 1901, with Dr. C. A. Runyon. Had middle-ear disease on the right side for one and one-half years. For four months had indisposition for exertion and tendency to melancholia, for six weeks had been considered seriously sick with typhoid fever. For four weeks he had shown evidence of serious cerebral disturbance and absence of the old discharge from the ear. Was at times maniacal and intolerant of all restraint. Emaciation was pronounced; paralysis almost complete on left side for four days; temperature 98½°, pulse 72 for four weeks. Had been taking nourishment well for several days, and operation was postponed for relief from the cerebral abscess, which was diagnosed, in the hope of making some gains in his physical condition, which was precarious in the extreme for any heavy surgical procedure. Mind clear, but sluggish in action. September 7, 1901, had convulsion and died in a few moments.

The report of the post-mortem examination by my first assistant, Dr. W. G. Doern, and Dr. C. A. Runyon, September 7, 1901, is as follows:

"O. P., Elvaston, Ill. Body greatly emaciated. Rigor mortis marked. Scalp peeled away from incisions made from one mastoid process to the other. Cap of skull removed with saw. Upon removal of skull cap, dura mater was found engorged with venous blood. Area about two inches in diameter over temporosphenoidal lobe, bulged about one-fourth inch beyond general contour of brain. With rougeur, gnawed away bone down to right mastoid process and proceeded to remove brain from before backward. Upon separating attachment of dura to right petrous portion, pus was evacuated from abscess. Upon removal of brain, found opening one-fourth inch in diameter in the roof of tympanum. Walls of tympanic cavity covered with soft granulation tissue; tympanic membrane almost entirely destroyed. Tympanic cavity had been filled with cotton by undertaker. Mastoid cells not involved. Opening was through dura mater directly over tympanic cavity, on right side, the margins of which were firmly attached to the petrous bone. The first abscess cavity was filled with about four ounces of yellowish white pus; had no distinct fibrous wall; ruptured in removing brain. The second abscess presented in the margin of the cavity of first abscess, as a fibrous sac about one inch in diameter, also contained about one ounce of yellowish white pus. Abscess was surrounded by an extensive area of degeneration. The degenerated brain tissue appeared as a white semi-solid mass, which gradually shaded off to normal brain tissue. The left side was apparently normal. The right temporosphenoidal lobe practically entirely destroyed. The ventricles were not examined."

---

* Read at a meeting of the Iowa Union Medical Society, December 10 and 11, 1901.

Two of these cases make me feel that all was not done for their relief that should have been done. In the first case I was free of blame, for I urged operation, which was declined. In Case III. I was culpable for not urging immediate operation, but erred in judgment. I wish to urge that, in every case of middle-ear disease in which cerebral symptoms develop, accompanied or not by suppression of the discharge from the ear, the skull should be opened and search made for an abscess. If the search be properly made, no harm will result. A small director or good-sized hypodermic needle, with a point well rounded, so it will displace rather than cut, can be passed into the brain, straight, almost any number of times, without serious harm. In every case of suspicion of involvement of the mastoid, it should be opened thoroughly, starting with the attic, and, if need be, continuing backward and downward to its extremest limitations, to evacuate all infected areas. In such cases severe cerebral symptoms will, at times, be permanently relieved, and trephine operations above entirely obviated.

Case IV.—Guy F., aged ten years, of Leighton, Ia., referred by Dr. Payne, August 29, 1901, four years ago had scarlet fever with middle-ear disease as a sequel. Discharge was continuous, until, fifteen days previously, it abruptly ceased. Temperature ran up to 105° F. Large swelling occurred about the ear, extending down, on to the neck, over the mastoid, and far up over the temporal region. This was opened and drained by Dr. P. There was great tenderness on pressure. The parotid and cervical glands were enlarged. The facial nerve was paralyzed. On August 29, 1901, the mastoid was freely opened by me, and large mass of granulation tissue and necrosed bone removed, the granulation tissue being cleared out also from the tympanum. The sigmoid sinus was exposed for at least an inch, but not lacerated. Severe cerebral symptoms developed, ten days later, and continued for four days, which led to preparations for trephining; but free spontaneous discharge of pus through the wound gave immediate relief, and recovery was thereafter uninterrupted. The facial paralysis has entirely disappeared.

Serious consequences could be avoided in many, if not all, of these cases of middle-ear disease, if the membrana tympani was removed sufficiently to provide free drainage. The dangerous complications arise from granulation material filling the tympanum, and plugging the drainage point through the perforation of the tympanic membrane and auditory canal, leading to meningitis, thrombosis of sinuses, abscess in the cerebrum or cerebellum. For the above reasons the tympanum must always be kept clear of obstructive granulation tissue.

"Spotted Fever" in Montana.—A disease is prevailing in Bitter Root Valley, Mont., the nature of which is not known, but which has caused considerable alarm because of its great mortality, nearly every case having terminated fatally. The State Board of Health is now making an investigation to determine the nature and cause of the malady.

A REPORT ON EXPERIMENTS MADE WITH CARGILE MEMBRANE, FOR THE PURPOSE OF DETERMINING ITS VALUE IN PREVENTING THE FORMATION OF PERITONEAL ADHESIONS.*

By ROBERT T. MORRIS, M.D.,
NEW YORK.
PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

On March 8, 1900, I received from Dr. Charles H. Cargile of Bentonville, Ark., a package of what he called "sterilized animal membrane," and with it a letter requesting me to give the material a trial in the field in which Senn's omental grafting would be of service. Dr. Cargile wrote that his experimental tests had not been conducted among sufficiently favorable surroundings to bring out the practical value of the idea. The form of animal membrane that he had chosen was a particularly thin gold-beater's skin, made from the peritoneum of the ox. It had been subjected to heat-cumol sterilization by Mr. Kilmer of the firm of Johnson & Johnson, and was prepared in the form of a folded sheet in a sealed paper package. Shortly after receiving the material I applied it in a case of pyosalpinx, for the purpose of keeping separated peritoneal adhesion surfaces apart. The patient was of the sort that disappears from view after leaving the hospital, and the matter dropped out of mind until December, 1901, when I had a particularly troublesome case of extensive recurrent adhesions, following a peritonitis from appendicitis.

An operation for the purpose of separating adhesions had been done previously, and at that operation the whole of the adherent and disorganized omentum had been removed. The long stump of omentum again became adherent, in spite of the application of the aristol film method of treatment, and the patient was becoming a morphine habitué, though a woman of strong will and definitely opposed to the use of drugs for the purpose of relieving her discomfort. After separating the adherent stump of omentum, strips of the Cargile membrane were applied over all surfaces that had lost their covering of endothelium. It was observed that the membrane became intimately adherent at once, and that it appeared much like a normal peritoneal covering. The abdominal incision healed by primary union, and the subsequent relief from adhesion complications was so well defined that I planned a series of experiments in order to settle several questions that naturally came to mind. It was important to know how long the Cargile membrane resisted absorption, what became of it eventually, and to know if the membrane itself added any element of danger in the application. In order to make the experiments cover a wider range, I asked to have some chromicized membrane, and also some sheets of thicker vellum prepared. It was assumed that a material for preventing the formation of peritoneal adhesions should be unirritating, that it should be sufficiently durable to resist absorption until enough time had elapsed to allow new endothelial cells to cover denuded surfaces, and yet not so durable as to stimulate the peritoneum to encapsulate the mass. Further, it should not furnish an introduced culture medium for saprophytes.

The experiments were made upon rabbits at the Physiological Laboratory of the College of Physicians and Surgeons, where the facilities for research work planned by Dr. John G. Curtis furnished opportunity for proper detail work.

---

*A paper read at the meeting of the Surgical Section of the New York Academy of Medicine on April 14, 1902.

The assistants were my associate, Dr. L. A. [illegible] and Mr. John J. Hunt. The same general course of procedure was adopted with all of the rabbits. An animal having been anæsthetized, the fur was removed closely from the abdomen by means of an ordinary depilatory. Normal saline solution was employed for cleansing purposes in the course of operative work. Hands and instruments received the customary aseptic preparation.

The abdominal incision was closed with catgut or with silk, as specified in the notes, and the wound was sealed with collodion. Typical specimens removed at various times later were given to Dr. A. J. Lartigau, who prepared them for examination to determine the ultimate fate of the Cargile membrane in the tissues. A separate report will be made upon this part of the investigation.

Ten of the twelve rabbits were apparently little disturbed by the operative work. One rabbit died while under the influence of the anæsthetic. One rabbit suffered from the effects of bichloride of mercury poisoning, as stated in a subsequent note.

The following experiments and observations were made:

January 15, 1902.—Rabbit No. 1. Adult white male. Colon scarified with a needle over an area about one and one-half inches square. Cargile membrane applied over the scarified area and sutured in place with a suture of fine silk at each angle. Abdominal wound closed with No. 1 silk.

Rabbit No. 1 killed three days later. Observation: Primary union of the abdominal wound. Membrane and surroundings lightly adherent to all nearby peritoneal surfaces with loose, transparent coagula of lymph. Membrane area of colon apparently contracted to perhaps four-fifths of its original dimensions. The membrane seemed to be incorporated in the bowel wall, excepting at one point, where a bleb about as large as a pea containing lymph was elevated above the common level. Question: Are the abundant lymph coagula finally absorbed, or will they remain to cause permanent adhesions?

January 15.—Rabbit No. 2. Adult gray male. Question: Will Cargile membrane seal in an infected area, or will it become itself infected, and add an element of danger? Experiment: Incision about one-quarter inch long made through colon wall. Fecal matter allowed to escape. Opening closed with a Lembert suture. Fecal matter wiped away, but no special cleansing done. An area of colon round about the incision scarified for an area of about one and one-half square inches. Cargile membrane applied, and held in place with four silk sutures. Abdominal incision closed with silk.

Rabbit No. 2, killed one week later. Observation: Primary union of the abdominal incision. Membrane area contracted to apparently three-fifths of its normal dimensions. No peritonitis. No adhesions found about the site of the membrane, excepting one unimportant thread. Membrane intimately incorporated in bowel wall, excepting at a point directly over the colon incision, where a small bulla raised above the surface contained a clear lymph coagulum. Conclusion: Membrane can wall in an infected area without itself becoming an added culture medium.

January 15.—Rabbit No. 3. Adult white male. Question: Can the membrane seal in a necrotic area of bowel? Experiment: An area of colon wall about one and one-half inches square was rubbed with a tablet of bichloride of mercury. Membrane was applied evenly over the injured area, excepting at a small space left purposely exposed for comparison. Silk closure of abdominal wound.

Rabbit No. 3 killed three days later. (It was intended to keep him for a week, but the animal was evidently suffering from bichloride of mercury poisoning, and was very ill. An incidental note may be of interest in the fact that this ill rabbit seemed to be almost chloroform proof, and several minutes' exposure to chloroform vapor, with practically no admixed air, was required.) Observation: Intense general peritonitis. Large firm opaque lymph coagula about the margins of the membrane held it in place, and there were loose adhesions at various points in the peritoneal cavity, together with much free serum. The membrane was not adherent to or incorporated in any part of the colon wall. Superficial necrosis of all of the bowel wall that had been exposed to the action of bichloride of mercury. Conclusion: An inflammatory process may be sufficiently marked to prevent the adherence of the membrane, and in that case the membrane would remain for some time as a loose foreign body in the peritoneal cavity.

January 15.—Rabbit No. 4. Adult gray and white male. Question: What becomes of membrane allowed to remain loosely in the peritoneal cavity, without the lymph adherence furnished through scarification of peritoneum? Experiment: A strip of membrane three by one and one-half inches, fastened to colon by two silk sutures at one end, allowing the remainder of the strip to hang free. No scarification of peritoneum. Abdominal incision closed with silk.

Rabbit No. 4, killed five days later. Observation: Primary union of abdominal incision, membrane lightly adherent to various loops of bowel by a few loose transparent lymph coagula. No evidence of other disturbance of peritoneum. Conclusion: Membrane undergoes practically no change during five days of exposure, and its presence is not a source of much irritation to the peritoneum. In so small an animal as a rabbit a foreign body of the size of this strip of membrane used in the test would naturally appear to be rather formidable, and the absence of more extensive evidences of irritation caused by its presence seems to be significant.

January 22.—Rabbit No. 5. Large white pregnant female. Question: Will the membrane prevent the formation of the common and troublesome adhesions which form along the line of suture after some of our simplest abdominal operations? Experiment: Incision in middle abdominal line three inches long. To the right of the line of incision the peritoneum of the abdominal wall was scarified for a width of one-half inch and a length of three inches. A strip of membrane three inches long and two inches wide was laid upon the subjacent loops of bowel, and the abdominal incision closed with large silk sutures (No. 3), which were allowed to extend so far over the peritoneal surface that local adhesions would have been assured under ordinary circumstances. In addition to using coarse silk, the silk was allowed to trail over the fur of the rabbit in order to introduce a moderate degree of sepsis.

Rabbit No. 5 killed forty-five days later. Observation: Abdominal incision firmly closed, but carrying several foci of infection with nodules of encapsulated cheesy pus. No adhesions anywhere within the peritoneal cavity. The silk sutures plainly visible beneath what appeared to be new and normal peritoneal covering. Where nodules of suppurating foci had projected within the abdominal cavity, their surfaces were covered benignly with normal-appearing peritoneum. No sign of the membrane remaining, excepting opaque blotches upon the bowel wall, at which points the membrane had evidently adhered during the progress of its absorption. Conclusion: The membrane can serve to prevent adhesions between bowel and abdominal wall, under a most severe test.

January 22.—Rabbit No. 6. Small brown female. Question: If loose adhesions form, as in experiment with rabbit No. 1, are these adhesions soon absorbed? Experiment: Scarification of an area of colon wall about one inch square. Segment of membrane two inches long by one and one-half inches broad, applied without sutures. Abdominal incision closed with small catgut.

Rabbit No. 6, killed forty-five days later. Observation: No adhesions and no trace of membrane remaining. A single short string of lymph dangled from the abdominal wall. Conclusion: The membrane can protect against such adhesions as would certainly form after scarification of the bowel wall under ordinary conditions, and no evidence of the presence of the membrane was left at the end of forty-five days in this case.

January 22.—Rabbit No. 7 took the anæsthetic badly and suddenly expired under its influence.

January 22.—Rabbit No. 8. Medium-sized white male. Experiment: Repetition of experiment with rabbit No. 6, but observation made at the end of ten days instead of at the end of forty-five days.

Observation: Primary union of abdominal incision. Loose, transparent adhesions about the site of the membrane, including parietal peritoneum and that of bowel near by. Membrane intimately adherent to the scarified area of bowel wall, and succulent looking, but apparently not as yet becoming absorbed. Conclusion: The membrane resists absorption for considerably more than ten days.

February 1.—Rabbit No. 9. Large brown male. Question: How does chromicized membrane behave in the peritoneal cavity? Experiment: Scarification of area of colon wall one inch by one and one-half inches. Chromicized membrane applied to scarified area without sutures. Abdominal incision closed with catgut.

Rabbit No. 9, killed thirty-six days later. Observation: Primary union of abdominal incision. One trifling string of adhesion near membrane site. Membrane area barely distinguishable, the material apparently smoothly incorporated in bowel wall or absorbed completely. (Pathologist's report will describe this specimen.) Conclusion: Chromicized membrane probably possesses no advantages or disadvantages as compared with simply prepared membrane.

February 5.—Rabbit No. 10. Large brown male. Repetition of experiment with rabbit No. 9.

Rabbit No. 10, killed thirty-six days later. Observation: Primary union of abdominal incision. No peritoneal adhesions anywhere. Membrane area elevated above the surrounding peritoneal level, but the membrane apparently benignly incorporated in bowel wall. Conclusion same as with rabbit No. 9.

Rabbit No. 11. Adult white male. Repetition of experiment with rabbit No. 1, with longer time observation.

Rabbit No. 11, killed thirty-one days later. Observation: One unimportant adhesion thread remaining near the scarified area, but the membrane evidently absorbed, excepting for a loose tag hanging from the bowel. This latter was succulent-looking, and was probably a part of the membrane that had not become engaged in the scarification lymph, and was probably undergoing absorption more slowly on that account.

February 5.—Rabbit No. 12. Large brown male. Experiment: First, a repetition of experiment with rabbit No. 11. In addition, an intussusception of ileum was made by touching the bowel with carbonate of sodium, and when the intussusception had formed the area was surrounded with a strip of membrane.

Rabbit No. 12, killed thirty-one days later. Observation: Primary union of the abdominal incision. No peritoneal adhesions. Scarified area of colon barely distinguishable. Intussusception area of ileum much thickened, and the peritoneum grayish in appearance at that point, but the intussusception had not progressed, and the Cargile membrane had left no sign of its presence unless in the gray coloring of peritoneum.

Remarks: The fact that suppuration occurred in the one case only in which it was intended that it should occur, is evidence of the care given to aseptic details by my assistants. Cargile membrane seems to resist absorption in the peritoneal cavity for more than ten days and less than thirty days. Its presence apparently causes the formation of temporary loose adhesions, which are harmless, and which become absorbed for the most part in less than thirty days. The membrane seems to cause very little disturbance to the peritoneum, it does not furnish a good culture medium for bacteria, and it protects areas of peritoneal surface that have suffered injury to their endothelial covering, until new endothelial cells have repaired the injury without involving neighboring peritoneum.* It is not necessary to suture the membrane in place, as it becomes instantly adherent to moist surfaces, and is not readily dislodged afterward. In this connection it may be well to give warning against handling the material with wet hands or instruments.

In addition to the experiments in the peritoneal cavity, I have applied the membrane for a variety of purposes in wound treatment. As an animal membrane it seems to be particularly agreeable to the tissues of open wounds. It serves as an excellent conductor of epithelium when placed next the wound beneath absorbent dressings. It is not impervious to moisture, and in that regard possesses advantages over gutta-percha tissue or silver foil. In brain surgery the membrane adheres closely to exposed brain tissue, and it makes a very good *dura mater* for temporary purposes. It can be used to keep severed and sutured tendons from uniting *en masse*. I have had no opportunity to employ the Cargile membrane in plastic eye surgery, as few of these cases get to my clinics, but from our knowledge of the value of this material as a conductor of epithelium and of endothelium it would seem to offer advantages in this special field.

---

*The pathologist's report will show whether new endothelial cells or new connective tissue cells conduct repair.

Case of Saddle-Nose Treated by Subcutaneous Injection of Paraffine.—Scanes Spicer reports the case of a woman with a well-marked tip-tilted saddle-nose with stunting of the nasal framework. Sterilized paraffine was injected, with the result of a very palpable bolstering up of the skin over the bony bridge of the nose, and the formation of a very decent-sized organ. The operation was done ten months ago, and the nose remains in the same state as when first injected. The paraffine used was a mixture of hard and soft paraffine, made to melt at 105° F. Ten or twelve syringefuls were injected under the skin, some downward over the nasal bones, some upward from the sides of the nose into the depressed gap, and the injected paraffine was moulded by an assistant's fingers, so as to shape the part before setting.—*The Clinical Journal*, April 9, 1902.

Black-water Fever and Quinine.—P. Rowland takes exception to the conclusions [illegible] on the [illegible] supported by him. [illegible] that the continued administration of quinine is [illegible] since it has been amply demonstrated that black-water fever is due to the [illegible] effects of quinine. The cardinal principles of treatment in this condition are [illegible] and [illegible] the production of an [illegible] by the administration of large quantities of fluids. Black-water fever is not so fatal a disease as is generally supposed when it is properly handled [illegible]. The [illegible] observed [illegible] only one of which terminated fatally, and this one was complicated by a severe form of tropical dysentery. After [illegible] Rowland [illegible] was seized with black-water fever as the result of the ingestion of quinine, but [illegible] recovered when treated on the method here described. Especial emphasis should be laid upon the immediate discontinuance of quinine as soon as hemoglobinuria appears. It is best that the patient should never again take this drug, although it may be resumed after months if absolutely necessary, and if its administration is conducted with great care.—[illegible] *[illegible]*.

The Clinical Significance of Leucocytosis in Pleurisy.—John T. Hewetson finds that suppurative pleurisy produces a very definite leucocytosis of the polynuclear finely granular variety. Pent-up suppuration, of the acute pyogenic character, is almost constantly associated with a leucocytosis. Not only is there a great increase of the white blood corpuscles at the seat of the inflammation, which act as the first line of defence, but there is also a pronounced increase of the circulating leucocytes which act as the reserve force upon which further demand may be made. This general leucocytic increase can be accurately measured without the least difficulty and it follows so closely the precise progress of the local suppuration that its regular estimation furnishes an important clinical guide in the study of this common surgical malady. In many deep suppurations, especially those associated with abdominal organs, the labor entailed by examination of the blood would be amply repaid. More than one of the cases reported by the author had vague and obscure symptoms and were regarded as tuberculous and beyond the pale of surgical resource until this aid to diagnosis was employed. There should be a more frequent use of the Thoma-Zeiss hemocytometer in surgical practice.—*The Birmingham Medical Review*, April, 1902.

"Solar Cautery" in the Treatment of Cancer, Lupus and Other Malignant Growths.—O. V. Thayer says that during a practice of more than forty years he has not known or used any remedy to be compared with solar heat in its curative power. In the treatment of morbid and malignant disease the tissue must be most fully destroyed or carbonized. Upon this depends the success of the operation. The tissue must be thoroughly desiccated by applying the solar heat for only five or ten minutes at first time—this dries out the fat, blood and serum. After waiting a short time for the part to cool, the application is renewed and continued from time to time until the object is accomplished. In the treatment of cancer and allied diseases by the use of concentrated sun's rays, we possess a remedy at once safe and curative, attended with little pain and inconvenience. Not more than twenty or thirty treatments are required. The wound soon heals with little trouble, and the skin is, in great measure, restored to its normal condition. The author reports several cases of malignant growths successfully treated with concentrated sun's rays.—*[illegible] Medical Journal*, April, 1902.

The Neuropathological Aspects and Neurotherapy of Marasmus Infantilis.—Charles H. Hughes offers the following therapeutic precepts: (1) A clean prima via as [illegible] may be practicable without harm to the patient. (2) [illegible] to mouth and skin. (3) Normal blood pressure restored with normal salt solution per rectum and [illegible]. (4) Judiciously regulated [illegible] slightly above the normal for [illegible] fants and adapted to the [illegible] of each case. Regulated light. (5) Cautious general [illegible] and [illegible] to stimulate cell activity, neural and epithelial. [illegible] and [illegible] (6) Such attention to the diet as will best promote [illegible] and [illegible] Alcoholic [illegible] and [illegible]. [illegible] should be [illegible]. [illegible] should be reduced [illegible].—*Medical [illegible]*, April 15, 1902.

The Etiology of Typhoid Fever.—Thomas Cherry concludes: (1) That many mild cases of fever, often classed as influenza, are slight attacks of typhoid, and may serve to distribute the contagion. (2) Typhoid fever itself may be a composite disease, or series of diseases caused by closely allied organisms. (3) While from the bacteriological evidence the *de novo* origin of the disease is not disproved, still a general survey of all the known facts enables us to explain most cases without having recourse to this hypothesis. (4) Typhoid fever at once disappears from a community with the introduction of a proper system of disposal of excrement and household refuse. In towns this can best be done by a properly constructed water-carriage system of sewerage. (5) The disease is spread chiefly by the contamination of water, milk and other articles of food. In hot countries at least, flies and dust have a share in bringing about this contamination. (6) The length of time during which the bacilli can exist outside the body is unknown. There is evidence to show that the contagion hangs about old cesspits and contaminated soil for several years.—*Intercolonial Medical Journal of Australasia*, March 20, 1902.

Electric-Light Conjunctivitis.—Harold B. Grimsdale describes the case of a laborer who, while engaged in repairing an arc lamp which was giving light all the time, noticed during the process that the after image of the lamp was very troublesome. When he reached home he was attacked by great photophobia and lachrymation, but there was no blepharospasm. Visual acuity was found to be 6–18. The cornea was clear and bright, around its margins, however, were a few small papules, such as often indicate the first stage of phlyctenulæ. Cocaine and cold compresses overcame the photophobia in about twenty-four hours, and the lachrymation and injection yielded to boric acid within a few days. The author also reports several other cases. The conjunctivitis is probably due to a disturbance of the nervous system, and especially the vascular centers, by direct stimulation of the afferent nerves, or else the rays must cause some chemical change in the conjunctiva whose products act as strong irritants producing the local inflammation. The former is the more probable.—*Medical Times and Hospital Gazette*, April 12, 1902.

Acquired Deaf-mutism Probably Due to Impacted Cerumen in the Ear.—Mayo Collier reports the case of a child that, at the age of three, had appeared to be deaf and to lose the power of uttering intelligible sounds. Nothing in the history pointed to any antecedent inflammation in the ears. Examination showed only impacted cerumen, which was syringed out. The ear was then politzerized. The drum membranes were found to be contracted and opaque, but otherwise healthy. Almost immediately the child began to show an appreciation of sounds and very shortly to resume its speech. Recovery was soon complete.—*Journal of Laryngology*.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

Publishers

WM. WOOD & CO., 51 Fifth Avenue.

New York, May 17, 1902.

TEMPERANCE AND TOTAL ABSTINENCE.

The Medical Record has always been an earnest advocate of temperance and has oftentimes drawn attention to the hurtful influence of intemperance regarded from the standpoint of the surgeon and the physician. The fact is too generally recognized to need emphasis, that an individual who has been accustomed to consume alcohol in excessive quantities is a bad subject to be visited by either sickness or injury, and that by such habits he has very considerably prejudiced his chance of a quick and favorable recovery.

The case against inebriety or even against the habitual and constant use of stimulants is clear and conclusive, and few, if any, scientific men of the present day would venture to defend the habit when indulged in freely. Nevertheless, there is a wide distinction between temperance and abstinence. Many extreme advocates of total abstinence hold that under no circumstances is alcohol of value, and that a person at all times, in sickness or in health, is better without it.

This question within the past few years has given rise to arguments and discussions of almost interminable length, not untinged with a certain degree of acerbity. The propagandists of total abstinence have been, like most reformers, dogmatic in their assertions and characteristically impatient and contemptuous of the opinions of those who hold opposing views.

However, a final decision has not as yet been reached and, probably, at the present time, the greater number of physicians believe rather in a moderate indulgence in alcoholic beverages at certain times than in entirely abstaining from stimulants of this nature on what is termed abstract principle.

The late Sir James Paget, who was a man endowed with an eminently sane and well-balanced mind, has given among his essays, recently published by his son, a well thought-out presentation of the subject. Since the time the paper was first issued—more than twenty years ago—opinions on the use of alcohol have undoubtedly undergone a change, but upon the whole a large proportion of medical men will find that the English surgeon's views do not widely differ from their own.

Sir James Paget in part said: "As for the opinions of the medical profession, they are, by a vast majority, in favor of moderation. It may be admitted that, of late years, the number of cases has increased in which habitual abstinence from alcoholic drinks has been deemed even better than habitual moderation, but, excluding those of children and young persons, the number of these cases is still very small, and few of them have been observed through a long course of years, so as to test the probable influence of a life-long habitual abstinence. Whatever weight, then, may be assigned to the balance of opinions among medical men, it certainly must be given in favor of moderation, not of abstinence."

The advocates of total abstinence have always made a great point of the assumption that the taste for alcohol is not natural but artificial or acquired, but have never been able to exactly state the strict definition of the word natural in this respect.

Sir James Paget claims that our natural state is that in which we now live; the present state is to each race of men, if not to every one man, the natural state—the state attained in the natural course of development. In this state men are disposed to drink alcoholic liquids, and the presumption must be that these drinks are beneficially adjusted to some of the conditions of our life, which have been obtained in our development from some less civilized or completely savage state. Considering how largely our nature has been changed from that state by the gradual developments of society and by the various habits, dispositions and capacities therewith associated, it is in the highest degree probable that, with these changes, we should have beneficial adjustments of different foods or other means of sustaining us in our work. Among these may be reckoned the greater part of the comforts, and what may now seem to be the necessities, of our civilized—that is, our natural—state, such as wheaten bread, potatoes, cultivated fruits and nutritious meats; and, similarly, among them may be considered, —unless there be clear reason to the contrary—such things as tea, coffee and alcoholic drinks, and even tobacco, though, probably, only for much smaller groups of men. Doubtless all these things are used by some persons in a mischievous excess, but so may be bread and cheese. With the advance of civilization and the consequent development of the human race, our manner of living, eating and drinking has adapted itself to our new environment.

The vegetable kindgom provided sustenance to the primitive man, and water was his sole drink, and he, probably, thrived well, but this does not prove that the same diet would be better for an individual of our generation under entirely different conditions.

Again, if drinking produced in a race the fearful evils which its opponents claim, and knowing to how great an extent the descendants of the intemperate suffer through inheritance, would not the bad results of moderate drinking have become strikingly evident. But such does not seem to be the case. At the present time the heirs of the moderate drinkers are, in bodily and mental vigor, superior to the heirs of the abstainers. Further even than this, the heirs of the races said to have been hard drinkers in times gone by are still in the van of progress and civilization. Abstinence enthusiasts argue that if a large amount of alcohol does great harm a smaller quantity must necessarily do harm to a lesser extent. Sir James Paget points out that the facts are the other way. Large quantities of quinine will make a man, at least for a time, deaf and blind; smaller quantities may do nothing of the kind, but may cure his agues and yet smaller doses may leave him with his agues and all his actions unaffected but may improve his appetite. One quantity of arsenic may kill any man; another much smaller may strengthen him or cure his neuralgia or some disease of his skin.

The conclusion arrived at by the distinguished English surgeon was that there was not sufficient evidence to make it probable that a moderate habitual use of alcoholic drinks was generally, or even to many persons, injurious, and that there were sufficient reasons for believing that such an habitual use was, under certain conditions, beneficial.

Atwater in this country, Reid in Great Britain, and many scientists of Europe have during recent years gone deeply into the question of the value or otherwise of alcohol to man, and have gathered from laboratory investigations and tests much more accurate information on the subject than was available at the time when Sir James Paget wrote. Nevertheless, there is by no means, even now, unanimity of opinion as to its physiological action, or its effects through heredity, and, perhaps, the calm, judicial and common-sense manner of regarding the use of alcohol manifested by Sir James Paget may not by many physicians be as yet regarded as out of date.

BERIBERI AND THE QUESTION OF DIET.

A REPORT received at the War Department from Captain Harry A. Littlefield, assistant-surgeon, on duty at the military prison of Lingayen, Pangasinan, Philippine Islands, treats of the apparent effect of diet upon the occurrence of beriberi among the native prisoners. The report says:

"Since the establishment of this prison until February 1 of this year the native prisoners have been supplied with Chinese white rice. During this time beriberi has been markedly endemic in the prison. The records of this office show that the number of deaths have averaged about five monthly, while the number of new cases was about twelve. When prisoners reported sick with beriberi they were removed from the prison to a building about one-half mile distant. The upper story of the building was used as a hospital, the difference in conditions existing at the beriberi hospital and the prison being only the higher elevation of the former. The diet supplied was the same at both places. Many of the patients at the beriberi hospital continued to grow worse and died. The majority of those who recovered did so after long illness and many of them suffered from numerous relapses. During the month of January there were thirty-five patients in the beriberi hospital and as many more in the prison were slightly affected. The sanitary conditions were excellent. In the civil prison, not more than one-fourth of a mile distant, there was confined a large number of natives and the sanitary conditions were not so satisfactory as those in the military prison. They were more crowded, in poorer buildings, and were not in the open air more than the natives confined in the military prison. In this prison there were no beriberi cases, the only difference existing in favor of the civil prison being in the ration, which was purchased in open market. In the beginning of February of this year, upon the recommendation of the prison surgeon, the use of the Chinese white rice, which is supplied by the commissary, was discontinued and native rice from the open market purchased in its place. Since this change no new cases of beriberi have developed among the military prisoners and no deaths have occurred. The old cases which were in the prison have all recovered. This marked change occurred in the period of one month, and the only apparent difference existing during this period and previous times was that of the rice supply. From these facts it would seem that the cause of beriberi in this prison has been brought about by the use of the Chinese rice—white variety."

There is much strong clinical evidence in confirmation of Assistant-Surgeon Littlefield's belief that the character of the ration, particularly in relation to its rice constituent, has much to do with the occurrence of beriberi, even though many good minds hold to the idea that the disease is communicable under certain conditions not as yet fully understood.

In the Japanese Navy beriberi was for many years the most potent cause of sickness, disability and death among the sailors. About a decade ago the Japanese naval ration was changed, the quantity of rice cut down one-half and barley substituted therefor. Since the time of the change in this ration beriberi has practically been absent from the Japanese Navy, only a fraction of 1 per cent of the cases occurring which formerly were present with the full rice ration. In Java the Dutch have found that beriberi is less liable to occur with a diet of red rice than of white rice; and in French Cochin China, outbreaks of the disease in prisons and among gangs of railroad laborers have been abruptly checked by cutting down the rice constituent of the diet and increasing the nitrogen and fat intake by substituting beans and fat meat therefor. If the infectious nature of beriberi be assumed, it may be that invasion by a specific organism can only occur in the presence of a certain dyscrasia and lowered vital resistance, depending upon an improperly balanced diet.

Investigation into the chemical composition of the food materials used by natives in the tropics, with careful study of their dietaries, would very possibly give valuable information in connection with the occurrence of beriberi, plague, and the other tropical diseases, which select their victims largely from the natives, and pass over the whites living at a higher nutritive level, but otherwise under similar conditions.

A Yale Professor Sued for a Mistaken Identification.—A swindler was working New Haven some weeks ago, leaving packages of worthless drugs at the houses of physicians while they were absent and collecting money for the same from the servants who received them. Among those victimized was Dr. O. T. Osborne, Professor of Materia Medica and Therapeutics at the Yale Medical School, and, seeing a man some time afterward at the railroad station whom he supposed to be the swindler, had him arrested. The man was locked up over night, but discharged the following morning for lack of evidence, and now sues Dr. Osborne for $10,000 damages for false imprisonment.

THE VOLCANIC ERUPTIONS AT MARTINIQUE AND ST. VINCENT.

The awful calamity attending the volcanic eruption at Martinique and the death of over 30,000 victims within a few seconds, stands unparalleled in history. The incidents, as described by survivors, exceed in horror anything that can be reasonably imagined. The wholesale slaughter can, however, be accounted for by the complete death-dealing conditions that prevailed. With a storm of fire, seething mud blazing cinders, stifling gases, and overpowering smoke, an entire population was stricken with almost instant death.

The majority evidently met their fate by suffocation from sulphurous fumes, carbonated and sulphureted hydrogen, and the carbonic oxide gases. It was seemingly, and for the most part, asphyxia primarily and burning subsequently. Many of the corpses found were face downward, with hands to mouth, as if the last act was to guard against the inhalation of mephitic vapors. Death under such circumstances is almost instantaneous, and virtually painless. The contemplation of this fact offsets, in some slight degree, the dire and awful results of the tragedy. Very many were, doubtless, burned to death by the overwhelming flood of lava, and the torrents of blazing cinders, but even under such circumstances it is a relief to believe that the agony was short.

It is not surprising to learn that the decomposition of the bodies has been rapid, as such is the rule when there is mere charring of the surface, and when incineration is not complete. The serious problem, from a sanitary standpoint, is the rapid disposal of this frightfully large accumulation of decaying animal matter. It can, with truth, be said that the town is virtually uninhabitable until the débris is properly disposed of. Cremation is obviously the most expeditious means to such an end, as was proven in the recent Galveston flood. Another plan, almost equally expeditious, would be that of wholesale burial at sea. The most difficult task of all, however, will be the necessary separation of the bodies from the molten piles of cinder débris, so that they can be properly destroyed by fire, instead of being, otherwise, only partially consumed under protecting heaps of ashes.

The St. Vincent disaster, occurring simultaneously with that of Martinique, and evidently due to the same subterranean disturbances, was attended with much less loss of life, but in most of the victims, so far as can now be learned, death was due to burns from the lava.

The Treatment of Consumption in High Altitudes.

The Sanatorium treatment of pulmonary tuberculosis has now gained so firm a hold in the estimation of medical men that it seems rather curious to consider that but a few years ago the method was almost unknown.

Davos Platz in the Switzerland Alps was, perhaps, the first place in Europe to win a reputation as a health resort for those afflicted with respiratory complaints, and it was not until 1870 that its fame came into prominence.

At the present time Davos is visited in the winter season by a larger number of weak-lunged persons than any locality in the world, and there are also a goodly quantity of invalid visitors in the summer.

According to the New York *Evening Post*, Davos was visited last year by 7,000 Swiss, an equal number of Germans, 3,000 English, and only 300 Americans.

The late Robert Louis Stevenson had something to do with rendering Davos popular, for during two winters he resided there, deriving much benefit from his sojourn.

Davos not only stands at an altitude of 5,000 feet above sea level, but is exceptionally well sheltered by natural barriers, besides which, in the winter, the air is still.

There are a number of sanatoriums and hotels, all constructed on the most approved plans. The treatment is such as is followed in the German sanatoriums—air, rest and food—and the benefit to health obtained from strictly proceeding upon these lines is said to have been remarkable in the case of a very large number of phthisical persons.

To a certain class of consumptive patients the effects of residing in high altitudes is beneficial in a marked degree, and no country in the world presents better opportunities for pursuing this mode of treatment under the most favorable conditions than does the United States. The mountainous districts of Colorado and other parts of this continent provide ideal situations for treating tuberculous subjects by these means, and it is strange that more advantage has not been taken of the natural gifts of America. Considering everything, the sanatorium system has not been pushed as it has deserved to be, and especially is this true with regard to the mountain regions.

This view of the case may be commended to the attention of millionaire philanthropists as well as to those who might wish to embark in the project from commercial motives.

Committee of the American Public Health Association to Investigate the Army Canteen System.

The Executive Committee of the American Public Health Association recently passed a resolution recommending the appointment of a special committee to prepare and publish, at an early date, a pamphlet for public circulation, containing the resolution of the Public Health Association in favor of the army canteen, together with a concise statement of the data upon which this action was based, and definite references to the original sources from which such information is obtainable; such pamphlet to be issued in the name of the association.

This recommendation was made in view of the fact: (1) That an important function of the American Public Health Association is to educate the public in matters of hygiene; (2) That the action above referred to is in disagreement with the ideas of a very large number of good citizens; (3) That this is a possible opportunity of securing their understanding of the action of the association, and, it is to be hoped, their intelligent coöperation in taking successive steps toward the betterment of existing conditions.

In compliance with the above resolution, the following representative committee has been appointed:

Chairman, Dr. C. A. Lindsley, ex-President of the American Public Health Association; Secretary, Connecticut State Board of Health, New Haven, Conn.

Members: Dr. Geo. M. Kober, Professor of

Hygiene, Georgetown University, Washington, D. C.; Dr. S. H. Durgin, ex-President of the American Public Health Association, Health Officer of Boston, Mass.; Dr. Helen C. Putnam, Providence, R. I.; Dr. Jefferson D. Griffith, late Chief Surgeon, U. S. Volunteers, Kansas City, Mo.; Mr. Henry Lomb, Rochester, N. Y.; Dr. J. H. Huddleston, Surgeon National Guard, State of New York, New York City.

It is understood that this committee will inquire into the causes which led up to the establishment of the canteen system in the army, the results of this system as observed during the decade of its existence, and the effect of its late abolition upon temperance and morals in the military service.

THE CASE OF HOSPITAL NURSES.

HOSPITAL nurses during the past two or three years have been severely criticized from various quarters, and as a class have been subjected to scathing indictments. In the United States the conduct of the nurses in certain hospitals constituted a public scandal, and it was loudly proclaimed by some reformers that the only way to place affairs upon a satisfactory footing was to dispense with the services of male nurses and to permit women alone to have the care of the sick.

The plan, however, judging from accounts from Great Britain, would by no means necessarily ensure the best results. Grave dissatisfaction with the manner in which nurses on the other side fulfil their duties has of late been widely expressed in the English public press.

Miss M. F. Johnston in the *Nineteenth Century* discusses the matter from the English standpoint. The writer freely allows that most of the charges brought against nurses are justified by the facts of the case. The English nurses, as a body, are callous and indifferent in their behavior towards patients and do their work in a perfunctory way and with a marked lack of human interest. They are far too apt to regard patients in the light of cases interesting as medical or surgical studies but otherwise of no particular concern.

Miss Johnston's diatribes are more especially directed against nurses sent to do duty in private houses, where, she declares, they are often more of a nuisance than a benefit and are wholly inconsiderate in their demands and offensive in their general behavior, while their callousness to suffering and the indifference they display, even in the hour of death, amount almost to brutality. The nurse recognizes that she is mistress of the situation, and frequently abuses her position to the utmost limits.

There is, nevertheless, another side to the question, and although the shortcomings of the nurses are undeniable, yet it is after all more the fault of the system than the individual. Hospital nurses in Great Britain are systematically overworked, and it may also be added underpaid. They work seven days in the week and are seldom given a rest, and as probationers are compelled to do menial labor, more or less degrading to a moderately cultured or refined woman.

But the greatest of all the drawbacks to a British hospital nurse is the lack of thorough training and of efficient supervision. No one is actually responsible for her capability as a nurse when her apprenticeship is over, and consequently it is somewhat of a lottery as to whether she is well-trained in her duties or not.

The remedy for this condition of things would be obviously the establishment of training schools for nurses, a certificate from which would be a guarantee of efficiency.

News of the Week.

The Southern Medical Association of Manitoba.—At the annual meeting of this society, held at Brandon on February 26, the following officers were elected: *President*, Dr. L. M. Mores of Brandon; *secretary*, Dr. Leslie of Alexander; *Executive Council*, Drs. Poole of Neepawa, Goodwin of Elkhorn, Thompson of Douglas, and Macdonald and McDiarmid of Brandon.

Suit Against a Physician for Revealing a Professional Secret.—A man in Rochester, N. Y., who was sued for $25, the balance of an unpaid bill, by his physician, has brought a counter suit for $5,000 for alleged breach of professional secrecy. In the complaint of the physician was a paragraph asserting that the services were rendered during the treatment of the patient for morphinomania. It is claimed that this statement was made in the course of a judicial proceeding and was consequently privileged.

Mississippi Valley Medical Association.—The next meeting of this society will be held in Kansas City on October 15, 16 and 17, under the presidency of Dr. S. P. Collings of Hot Springs, Ark. Dr. C. B. Parker of Cleveland, Ohio, will deliver the address on surgery, and Dr. Hugh T. Patrick of Chicago that on medicine. Those intending to read papers should send the titles of the same to the secretary, Dr. Henry Enos Tuley, 111 W. Kentucky street, Louisville, Ky., at as early a date as possible to obtain a favorable place on the program.

The Tri-State Medical Society of Alabama, Georgia, and Tennessee will hold its fourteenth annual meeting at Birmingham, Ala., on October 7, 8, and 9, under the presidency of Dr. J. C. Le Grande of Birmingham. The secretary is Dr. Frank Trester Smith of Chattanooga, Tenn.

A Yellow Fever Commission.—Under special commission from the Surgeon-General of the United States Marine Hospital Service, Prof. George E. Beyer, Professor of Entomology at Tulane University, Dr. Oliver L. Pothier of the New Orleans Charity Hospital, and Dr. Parker of the United States Marine Hospital service sailed recently from New Orleans for Vera Cruz, where they will make an inquiry into the relation of the mosquito to yellow fever. The commission expects to continue its studies in Vera Cruz during the entire summer.

Cholera in the Philippines.—The following were the figures of the cholera statistics up to May 9: Manila, 867 cases and 706 deaths; the provinces, 2,452 cases and 1,805 deaths, giving a total of 3,319 cases and 2,511 deaths.

Mr. Hutchinson on Leprosy.—Mr. Jonathan Hutchinson of London recently returned from South Africa, where he went to investigate the cause and prevalence of leprosy. He has come back even more convinced than ever that the main cause of the disease is the use of imperfectly cured salt fish. Under exceptional circumstances, however, he says it may be contracted by the eating of food contaminated by a leper, but that it is otherwise neither contagious nor infectious. The measures suggested for the prevention of the disease are legislative control of the fish-curing establishments; the diffusion of information as to danger of communication; and the establishment of small isolation homes into which lepers should be induced to go during the stage involving risk.

Scarlet Fever Epidemic in Philadelphia.—Scarlet fever is prevalent in epidemic distribution in the southern part of Philadelphia, 103 cases being reported for the week ended May 3; thirty-seven of these occurred in one ward, while a large number were reported from neighboring wards. There has been a marked increase in the number of cases during the past few weeks. The type of the disease is mild and the rash is ill-defined. During the previous week eighty-seven cases were reported.

Philadelphia Hospital.—Dr. J. Arthur Standen has been appointed resident dental surgeon.

An Inveterate Opium Habitué.—The death of a man was reported recently in Philadelphia who, for forty years, was known to have taken "five cents' worth" of laudanum night and morning.

Pathological Society of Philadelphia.—At a stated meeting, held May 8, Dr. W. M. Coplin presented a communication entitled "Acute Dilatation of the Stomach, with Especial Reference to the Condition of the Elastica." He discussed the various explanations that have been suggested in connection with the etiology of this condition, and he demonstrated specimens showing distortion of the elastic fibers of the muscular layer of the stomach. Drs. W. E. Robertson and A. P. C. Ashhurst presented a specimen of "Multiple Gastric Ulcers and Peritonitis" obtained from a woman in whom the condition had not been suspected during life. Death resulted from rupture and the development of purulent peritonitis. Sections at the margin of one of the lesions disclosed appearances indicative of carcinoma. Dr. W. E. Robertson reported a case of "Malignant Adenoma of the Kidney with Albuminosuria." The growth was really believed to be an hypernephroma. In addition there was thrombosis of the ascendlng vena cava and of some of the tributary veins. Dr. W. T. Pickett presented a communication entitled "Subacute Combined Degeneration of the Spinal Cord with Pernicious Anæmia." He reported the case of a woman who presented the blood changes of pernicious anæmia, and in whom complete paraplegia occurred a week before death. Early in the history of the case the knee-jerks were exaggerated, but in its further progress symptoms of posterior sclerosis developed. On post-mortem examination and histologic study of the cord tracts of degeneration were found in the posterior and the lateral columns, and, to a small degree, also in the anterior columns. Dr. M. B. Hartzell read a paper entitled "Benign Cystic Epithelioma; Report of Two Cases." He suggested, on account of the diversity exhibited by the cases described under this designation, that probably several affections were included presenting a close clinical resemblance, but exhibiting distinct differences histologically.

Prize Essay on the Dangers from Self-Drugging with Proprietary Medicines.—The Colorado State Medical Society offers a prize of $25 for the best essay, for circulation among the laity, upon the dangers of self-drugging with proprietary medicines. The competition is open to all. Essays must be typewritten in the English language, must contain not more than 3,000 words, and must be submitted before June 15, 1902. Each essay must be designated by a motto, and accompanied by a sealed envelope, bearing the same motto, and enclosing the name and address of the author. The essay receiving the prize will become the property of the society for publication. Others will be returned to their authors. Essays should be sent to the Literature Committee, Dr. C. A. Graham, Secretary, Stedman Block, Denver, Colorado.

Reports on Scientific Subjects—The Daily Press.—Drs. Gottheil and Franklin, the authors of the interesting paper on "The Penetration of the Human Body by Ordinary Actinic Light," which appeared in the Medical Record of April 19, write disclaiming all responsibility for an article on the subject which appeared recently in the Sunday edition of one of the daily papers of this city. They say that they refused to talk with the reporter for publication, or to allow him to reproduce the pictures, or to use their machine to make others. He, however, obtained a machine elsewhere, and repeated the authors' experiments, and wrote an article which was published in the usual style of the Sunday press.

College of Physicians of Philadelphia.—At a stated meeting, held May 7, Drs. John H. Gibbon and S. Solis-Cohen presented a communication entitled "A Case of Long-standing Hepatic Abscess; Operation; Recovery." The patient was a man who gave a history of having been in South Africa and of having suffered from dysentery. He presented a large swelling in the right hypochondrium, with little elevation of temperature and slight leukocytosis. The intestinal evacuations were examined for amebæ, but none was found. The diagnosis lay between abscess and hydatid disease of the liver. Exploratory puncture disclosed the presence of pus, and on operation a large abscess of the liver was found, whose contents were evacuated and drainage provided for. Amebæ were looked for in the pus, but were not found. The patient recovered, but was lost to observation. Dr. Arthur V. Meigs read a paper entitled "Analysis of Human Milk the Basis of the Artificial Feeding of Infants," in the course of which he reiterated two propositions upon which he has insisted for many years, namely, that human milk contains 1 per cent. of casein—that is total proteids—and 7 per cent. of sugar, and that mother's milk undergoes no essential change during the first five or six months of lactation. Accordingly, in the preparation of artificial milk-mixtures, the proportions of the substances named should be taken as a guide, and these need not be changed during the period mentioned, although the amount administered is to be progressively increased in accordance with the needs of the individual child. Dr. Jos. E. Winters of New York, by invitation, opened the discussion, and while assenting to the propositions laid down pointed out the danger from the use of centrifugalized cream and from the process of sterilization, pasteurization, and the like as calculated to change the constitution of the milk disadvantageously. Other speakers, however, dwelt upon the value of scientific percentage modification of milk and the necessity for change in quality, as well as quantity, in accordance with the varying conditions in individual cases, and in the same case at different times. Drs. J. Dutton Steele and A. P. Francine read a paper entitled "An Analysis of Sixty-five Cases of Splancnoptosis." They dwelt upon the frequency of gastroytosis in varying degree, and in discussion the interference with the motor activity of the stomach, to which it gave use, its association with displacement of the colon, and the kidneys especially; the absence of distinctive change in the constitution of the gastric juice, the uncertainty of any relation to neurasthenia, and the occurrence of diastasis of the abdominal rectus muscles, were noted. Drs. Joseph Sailer and G. E. Pfahler read a paper entitled "Diagnosis of Aortic Aneurysm Illustrated by *X*-ray Photographs." In addition to the demonstration of actual aneurysms by means of skiagraphy, there was noticeable in many of the pictures a projection or enlargement at the left extremity of the arch of the aorta, in some instances associated with symptoms suggestive of aneurysm, such as episternal pulsation, tracheal tugging and reduction in the print. However in one case in which post-mortem examination was made an aneurysm was not found but merely a condition of atheroma, and it is to this, in conjunction with the elongation of the vessel resulting from its loss of elasticity, that the symptoms and physical signs are probably to be attributed.

A New Dental School at Harvard. Plans are completed for a new Dental School for Harvard to cost [illegible], and to be located on the northwest side of the new Medical School in Brookline. The new building will be three stories high, and will cover an area of 196 by 58 feet for the main building, and 72 by 54 for the annex.

New Police Surgeons.—Police Commissioner Partridge recently appointed as police surgeons Dr. Frank R. Oastler and Charles A. [illegible]. Their names appeared in first and second place on the eligible list prepared by the Municipal Civil Service Commission. The salary of a police surgeon is $2,500 a year, and he is entitled to a pension after a certain term of service.

The Memphis Hospital Medical College. A thoroughly equipped modern building has just been erected for this institution, the amphitheater having a seating capacity of 1,000. The number of matriculants for the session just closing was 605.

Medical Women in Russia.—According to an official report just published by the Medical Society of Moscow, there are 624 women physicians in European Russia. Women dentists are not included in this number. During the year 1900 there were studying at the St. Petersburg Medical Institute for Women 869 women, of whom the majority will pass the State examination next April. The Czar takes a great interest in the matter and every year distributes prizes and medals among the best students.—*Woman's Medical Journal.*

The American Congress of Tuberculosis. The sessions of this Congress have been postponed from May 12-14, the date originally set, to June 2-4. This change has been made to give to those taking part in the discussions an opportunity to attend the meeting of the American Medical Association at Saratoga, June 10-13.

Dr. Nathan G. Bozeman has returned to this city after an enforced absence of nearly three years, on account of illness, and has resumed practice at 167 East Seventy-first street.

Medical Society of the State of West Virginia.—The thirty-fifth annual meeting of this society will be held at Parkersburg on May 21-23, under the presidency of Dr. G. A. Aschman of Wheeling. The secretary is Dr. Wm. W. Golden of Elkins.

The American Proctologic Society will meet in fourth annual session at Saratoga on June 10 and 11, in the parlor of the United States Hotel, under the presidency of Dr. Charles Martin, of Cleveland, Ohio. The secretary is Dr. William M. Beach of Pittsburg. The society has a membership of nineteen.

A Cancer Hospital and Laboratory.—Mr. J. K. Caird of Dundee, Scotland, has given £18,000 for the erection of a cancer hospital. He also has guaranteed £100 annually for five years for a laboratory for cancer research.

The American Academy of Medicine.—The twenty-seventh annual meeting of the American Academy of Medicine will convene at the Kensington, Saratoga, June 7, at 11.00 A. M., and continue during Monday, June 9, 1902. A series of interesting and valuable papers is promised, covering a variety of subjects and not confined so closely to a symposium as has been the custom for the past few years. A feature of the meeting will be an address, by invitation of the committee, by Edward T. Devine, of the United Charities of New York, on "Co-operation of the Medical Profession in Charitable and Social Reform." It is expected to have a full discussion of this important subject immediately following the address. The President's address will be given on Saturday evening. The completed programme will not be ready until about the middle of May. Then it will be sent to those who will advise the Secretary of the Academy of their wish to receive a copy. The officers of the Academy are: *President*, Dr. V. C. Vaughan, Ann Arbor, Mich.; *Secretary*, Dr. Charles McIntire, Easton, Pa.; *Chairman Committee on Programme*, Dr. G. Hudson Makuen, Philadelphia; *Chairman Committee of Arrangements*, Dr. C. M. Culver, 36 Eagle St., Albany, N. Y.

The Plague at Brisbane. This disease still lurks in many of the Australian seaports. Dr. Wray, the health officer of Brisbane, died of the affection on May 8.

The Late Professor Kaposi.—The New York Dermatological Society, at a meeting held April 22, 1902, adopted the following resolutions:

Whereas, Professor Dr. Moritz Kaposi, an honorary member of our society, has been removed from us by death, be it

Resolved, That on the death of Professor Kaposi the Society has lost one of its most eminent members; one whose high professional attainments, scientific achievements, and work as a leader have made his name famous through the whole medical world.

Resolved, That our deepest sympathy be extended to his family in their great sorrow, and that a copy of these resolutions be sent to the family, and medical journals for publication.

Canadian Medical Association.—The annual meeting of this association will be held in Montreal on September 16, 17 and 18, 1902. The President is Dr. Francis J. Shepherd of Montreal, and the Secretary Dr. George Elliott, 129 John street, Toronto. Dr. William Osler of Baltimore, Md., will deliver the Address in Medicine, and Dr. John Stewart of Halifax, Nova Scotia, the Address in Surgery.

Association of American Medical Colleges. The next meeting of this association will be help in Saratoga Monday, June 9, at 10 a. m. The programme will consist of two portions, one of which is educational and open to visitors. The several members of the association of Southern Medical Colleges are invited to be present and take part in the discussion. The second part of the programme relates to the business of the association and will be taken up at the second session at 3 p. m. the same day. The following are the officers of the association: *President*, Victor C. Vaughan, Ann Arbor, Mich.; *First Vice-President*, Wm. L. Rodman, Philadelphia, Pa.; *Second Vice-President*, H. Burt Ellis, Los Angeles, Cal.; *Secretary*, Bayard Holmes, Chicago, Ill.; *Judicial Council*, Thos. Hawkins, Denver, Col., E. C. Dudley, Chicago, Ill.; and W. J. Means, Columbus, Ohio.

Medical Society of the State of California.—At the annual meeting of this society, held April 15 to 17, the following officers were elected for the ensuing year: *President*, F. B. Carpenter, San Francisco; *First Vice-President*, C. C. Wadsworth, San Francisco; *Second Vice-President*, D. A. Hodghead, San Francisco; *Secretary*, George H. Evans, San Francisco; *Treasurer*, E. E. Kelly. San Francisco; *Board of Examiners*, Dudley Tait, David Powell, D. E. Osborne, W. S. Thorne, R. L. Wilbur.

The Fourteenth International Medical Congress will be opened in Madrid, Spain, on April 23, 1903, and close on the 30th of the same month. Dr. Abraham Jacobi, having been requested by the officers of the Congress to form the American committee, has arranged that the plan devised by Dr. William Osler, which worked so well in preparation for the Thirteenth Congress, shall be followed also for the Fourteenth. Invitations to accept places on the committee have, therefore, been sent to the President of the American Congress of Physicians and Surgeons, the President of the American Medical Association, the presidents of the fourteen constituent societies and associations of the American Congress, the Surgeons-General of the Army, Navy, and Marine-Hospital Service, the President of the Canadian Medical Association, and the President of the National Dental Association. Acceptances have been received from nearly all of those invited. Dr. Howard A. Kelly of Johns Hopkins University will deliver the address at one of the general meetings of the Congress, and has chosen for his subject "The Passing of a Specialty." Dr. Ramon Guitéras has been appointed delegate to the Congress by the New York Academy of Medicine. The committee to date consists of Drs. W. W. Keen of Philadelphia, President of the American Congress of Physicians and Surgeons; John C. Wyeth of New York, President of the American Medical Association; R. H. Chittenden of New Haven, President of the American Physiological Society; Walter S. Christopher of Chicago, President of the American Pediatric Society; Joseph Collins of New York, President of the American Neurological Association; John W. Farlow of Boston, President of the American Laryngological Association; Samuel A. Fisk of Denver, President of the American Climatological Association; S. C. Gordon of Portland, Me., President of the American Gynecological Society; Geo. T. Jackson of New York, President of the American Dermatological Association; Horace G. Miller of Providence, President of the American Otological Society; Presley M. Rixey of Washington, Surgeon-General of the Navy; F. J. Shepherd of Montreal, President of the Canadian Medical Association; George M. Sternberg of Washington, Surgeon-General of the Army; O. F. Wadsworth of Boston, President of the American Ophthalmological Society; DeForest Willard of Philadelphia, President of the American Surgical Association; H. August Wilson of Philadelphia, President of the American Orthopedic Association; James C. Wilson of Philadelphia, President of the Association of American Physicians; Walter Wyman of Washington, Surgeon-General of the Marine-Hospital Service; Abraham Jacobi of New York, *Chairman;* and John H. Huddleston, 126 West Eighty-fifth Street, New York City, *Secretary.*

Surgeon Porter, U. S. A., Wounded.—During the recent United States Army expedition against the Moros of Mindanao, Major R. S. Porter, surgeon of the command, was severely wounded in the thigh. Reports of the fighting state that the wounded Moros in several cases stabbed those of our troops who were endeavoring to give them succor.

The Army Appropriation Bill, just passed, carries an appropriation of $200,000 to reimburse officers and enlisted men for medical expenses while on sick leave from April, 1898, to April, 1899. The payment of accounts of this kind was not approved by the Treasury officials, and, as a result, many physicians gave their services gratuitously, from patriotic motives, to the sick soldiers needing their care. Much of the money appropriated as above will find its way to the physicians of the country. The introduction and passage of this amendment as part of the army appropriation bill was entirely due to the efforts of the Legislative Committee of the American Medical Association, supported by the army medical authorities.

Health of the Army in the Philippines.—A report of the health of the army in the Philippines for the month ending March 15 gives the rate of constant sickness at 6.45 per cent. A considerable increase of typhoid fever was noted, but there was a marked decrease in the case of malarial fevers. Dysentery was the chief cause of death. Bubonic plague has so far not attacked the command, and has occurred only among the natives in Manila. In speaking of cholera, the report says that this disease has only occurred twice in an epidemic form in the Philippines, both times in the '70's. During the worst year of these epidemics nearly 30,000 persons lost their lives from cholera.

Obituary Notes.—Dr. CHAS. McDONOUGH died on May 5 at Reading, Pa., at the age of seventy-five years. He was a graduate of the medical department of the University of Pennsylvania.

Dr. JOHN S. MILLER of Philadelphia died of pulmonary tuberculosis, on April 29, in Denver, Col., at the age of forty-six years. He was graduated from Jefferson Medical College in 1881, and became a resident physician in the German Hospital. Subsequently he was elected assistant demonstrator of anatomy in Jefferson Medical College and one of the surgeons to St. Joseph's Hospital. He was also a surgeon to the Baltimore & Ohio Railroad, and was one of the surgeons that went to the relief of the sufferers in the epidemic of typhoid fever at Plymouth, Pa., in 1882, and also of the sufferers from the Johnstown flood. Two years ago he went to Denver on account of failing health, and became demonstrator of anatomy in Gross Medical College.

Dr. THOMAS F. RIEGEL died at Philadelphia of typhoid fever on May 6. He was graduated from Jefferson Medical College, and was one of the resident physicians in St. Joseph's Hospital.

Dr. LANSDOWN PENNOCK died suddenly at Ridley Park, Pa., on May 7 of apoplexy at the age of sixty years.

Notes on the Diagnostic Value of Blood Examinations.—C. F. Martin considers the examination of the blood of great value as an aid to diagnosis, but not sufficient for a diagnosis without regard for the other clinical signs. The counting of the blood cells and the estimation of the hæmoglobin are sufficient for all practical purposes, and the author considers that in the majority of cases one can obtain sufficient information from the microscopical examination with ordinary slide and coverglass of a freshly removed specimen of blood. In appendicitis a leucocytosis of over 20,000 has not been found in non-suppurative inflammations, either of the appendix or of the pelvic organs, but the reverse rule does not hold good, and one may readily get an absence of leucocytosis with extensive suppuration. The same is true in typhoid perforation. In treating cases of hemorrhage with shock, it would seem that surgeons are more justified in relying on their observations from the patient's general condition than on the percentage of hæmoglobin.—*The Montreal Medical Journal*, March, 1902.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

[illegible]

London, [illegible]

The discontent with the ways of the Asylums Board increases, and well it may when fresh [illegible] a charge of extravagance has been brought. The [illegible] of the [illegible] says the board has wasted many [illegible]. This and other charges were repudiated at the meeting last Saturday in a memorandum signed by the chairman of the board and the chairmen of the committees concerned. These gentlemen are usually [illegible] of the Local Government Board, and the representative [illegible] are not satisfied with these reasons, but think that full investigation is called for. The document was [illegible]. Meantime outsiders, who have to [illegible] the [illegible], want to know a number of things, such as why the cost [illegible] at the [illegible] should have risen 11 per cent. in two years, and other equally awkward questions. The weekly cost of patients in four of the board's hospitals has varied from 20s. 8d. to 51s. 6d. Surely this shows carelessness and extravagance too. In 1901 there were an extra 100 patients per day and an addition was made to the staff of 425 persons. In 1896, with a daily average of 10,400 patients, the total expenditure was £[illegible]. Last year the patients numbered 10,505, but the cost went up to £857,607. Now could ninety-one additional patients increase the cost by nearly a quarter of a million or over £2,400 a year for every patient?

The lectures at our colleges are usually rather dull and formal affairs and the audiences very small. But very important communications are sometimes made. The Lumleian lecturer is supposed to treat his subject from a clinical point of view, and ripe experience is a valuable qualification for the post in the Fellow to whom it is entrusted. This year Dr F. T. Roberts was the lecturer and took for his subject "The Comprehensive Study of Thoracic Phthisis." He used the phrase to indicate the importance of the fact that the morbid changes in consumption are seldom limited to the lungs, but that other organs are constantly affected, and sometimes from an early stage. Consequently it is our duty to study each case in all its aspects. The diagnosis of tubercle in the lungs should forthwith lead to a careful search for other tuberculous lesions. So I presume we should recognize any other departure from health, study the patient as well as his malady. The most interesting part of the lectures related to the clinical investigation, and if Dr Roberts rather extolled this he by no means undervalued scientific investigations, though he deprecated the reluctance often displayed to credit any observation that did not originate in the laboratory. So, while he admitted that in some cases the diagnosis of phthisis can be made from the detection of bacilli when the physical signs are uncertain, he emphasized the fact that in other well-marked cases the organisms were not found after repeated examinations, and he strongly objected to the practice of getting the patients to force something from the throat when there was little or no expectoration. The matter of the lectures was carefully arranged under various headings (A, B, C, etc., 1, 2, 3, 4, and so on), strongly reminiscent of the author's textbook, suggesting that it was more adapted to be read in the library than listened to.

It surely seemed somewhat superfluous to lay before his audience a digest of the symptomatology of phthisis, the ordinary methods of physical examination and so forth, an audience composed of the president and officers of the College of Physicians with a few Fellows, and here and there a member or licentiate who had strayed in.

A friend came to me the other evening straight from the meeting of the Otological Society, at which a most serious report had been received showing a frightful amount of deafness among poor children. This report was by Mr Arthur Cheatle, who had examined the ears of one thousand children in the Hanwell District School. More than half these children had defective hearing, and in a great number of these the defect had not been observed by the teachers. The middle ear was affected in 518, the internal ear in nine, and the external ear in forty-nine. Foreign bodies were found in the ears of eighteen (six boys and twelve girls), but all the children were unconscious of their presence. No less than 335 of these children had had a discharge from one or both ears, and eighty-eight of them were said to be, as it were, walking near a precipice, and six half over. Adenoids were present in 434. But the special lesions are of minor importance; the grave matter is the great amount of unsuspected disease of the ears among the rising generation. It must be remembered, however, that [illegible] children of the very poorest class of the London population. It would be interesting to [illegible] if the figures could be [illegible]. At the same time it is to be observed that Mr Cheatle's statements were supported by other members of the society who had made similar investigations, e.g. Dr. [illegible] at Liverpool and Dr. Murray at Greenwich, [illegible] per cent. and 40 [illegible] respectively. It seems time some steps should be taken to prevent the loss of health and capacity entailed by deafness and ear disease. In some countries doctors are appointed to the schools, and the examination of the eyes and ears of the scholars is an important part of their duties. Our school boards have wasted a good deal of money on [illegible]; it would appear more sensible to preserve the proper hearing.

What do we mean by the term rheumatism or rheumatoid? This is an old question with one, renewed by a case shown at the clinical evening of the Medical Society as one of infantile articular rheumatism with chronic enlargement of the spleen, liver and lymphatic glands, resembling those commonly considered as forms of rheumatoid arthritis in children, such as those recorded by Dr Still. The patient was a boy of four and three quarter years, with some enlargement of the knees and elbows as well as symmetrical swellings about the hands and feet, apparently due to infiltration into the periarticular tissues. Considerable limitation of movement in the cervical spine, which was thought to account for extreme movements of the eyeballs, giving the face at times a most remarkable appearance. Up to November 1900 the boy was well. He then had what was diagnosed as acute rheumatism. Slight febrile attacks had been noticed subsequently, and in November 1901 an attack of endocarditis with mitral injury occurred. It was this which made Dr P. Weber, who showed the case, think it more allied to articular rheumatism than to rheumatoid arthritis in adults, and as, perhaps, due to the microbe detected by Drs. Poynton and Paine, the clinical differences resulting from age, as tuberculosis in the young differs clinically from that disease in adults.

The case drew rather divergent opinions from those present. Dr Sansom thought it was either rheumatism plus something or else not rheumatic at all. The cardiac lesion he pronounced very slight if present. He did not consider the cases recorded by Dr Still as connected with rheumatism. Dr Cantley agreed on this point, and regarded the case as osteoarthritis, associated with rickets. Dr Rolleston regarded the case as rickets, the joint mischief being probably septic. He thought the heart clearly affected. Dr Morrison found no organic heart disease, and held the case to be arthritis in a rachitic child. Dr Poynton, who had investigated the case bacteriologically, had not found the microbe of acute rheumatism. He mentioned that cases suggesting rheumatism might occur in two forms, malignant and non-malignant. Dr Paine spoke of two forms and mentioned points suggesting an infective origin. Dr Allchin deprecated the term rheumatic being applied to such cases, and could not think age could modify the disease so much. Dr P. Weber admitted his patient was rachitic, but maintained the rheumatic origin of the joint affection. He said recent research tended to show that there was only one rheumatic poison, though the cases might differ clinically.

Now, after this I hope your idea of rheumatism is more definite; I cannot boast that my own is.

A great effort is being made to raise a large sum for the Prince of Wales Hospital Fund in order to be a gift to the King on his coronation.

The council of the Hospital Sunday Fund met on the 17th. Sir E. Hay Currie has been appointed secretary and Mr Gilhatt honorary secretary. The Lord Mayor hoped for a larger collection this coronation year.

The Saturday Fund has issued its report for 1901. It raised £21,517, an increase of £1,266 over the previous year.

The revised classification of causes of death adopted by the Registrar-General is being issued. It is based on the Nomenclature of the College of Physicians and, of course, contains many important changes—the former classification has been in use for many years.

NURSING IN PRIVATE ASYLUMS.

To the Editor of the Medical Record.

Sir:—In the last number of the Medical Record appeared a letter from Dr Starr calling attention to the need of trained nurses in private asylums and pointing out the lack of intelligent care that this defect entails.

I desire to supplement Dr Starr's mention of the training school for nurses at Bloomingdale (established in 1896) by pointing out that each of the fourteen large State hospitals for the insane in New York has a training school for nurses, the first of which was established at

Buffalo about twenty years ago. The yearly output of graduates from these fifteen (including Bloomingdale) training schools must be at least two hundred, so that there should be no difficulty on the part of any private asylum in securing an abundance of competent nurses, thoroughly trained in the care of the insane as well as skilled in general nursing, for, in the large asylums especially, these nurses obtain a wide general experience in the hospital, infirmary and surgical wards.

Lists of all the graduates of the State Hospital training schools are being prepared and filed at the office of the Lunacy Commission in Albany, so that anyone desiring their names and addresses can obtain them on application.

FREDERICK PETERSON, M.D.,
President of the State Commission in Lunacy.

Progress of Medical Science.

The Boston Medical and Surgical Journal, May 1, 1902.

Thrombosis of the Cavernous Sinus, with Report of Four Cases, Including One Cranial Operation.—Edwin Welles Dwight and Harry H. Germain conclude that, even if we allow for error in the cases reported, we must recognize thrombosis of the cavernous sinus as an extremely fatal condition. Death is due to septicæmia or to pyæmia, and in well-established cases, operation in one form or another offers the only hope of recovery. The author's case shows that an incision into one sinus instantly and completely relieved the interference with circulation in both. It also demonstrates the fact that such an operation is not especially difficult, that it can be done under almost primary anæsthesia, not associated with any degree of shock, finished within a few minutes (eight) and that the hemorrhage is easily controlled.

Problems Relating to Surgery of the Stomach.—William J. Mayo has found gastroenterostomy to be the most satisfactory operation. He has performed it eighty times with eight deaths. For cancer, with few exceptions, the palliation has been of such short duration as hardly to justify the operation. The hope of the future for cancer of the stomach is early exploration and extirpation. For benign conditions gastroenterostomy has the great advantage that it drains the stomach from the lowest point relieving the retention of obstruction equally with the painful contact which the food causes in gastric ulcer. The main thing, in either the anterior or the posterior operation, is that the opening should be low down, near the greater curvature. The author has had little trouble with primary pernicious vomiting for more than four years since he began this practice.

Journal of the American Medical Association, May 12, 1902.

A Voluntary Board of National Examiners.—Owing to the great diversity now governing the various State examining boards, W. W. Rodman advocates the formation of a national board, whose members shall serve voluntarily. Upon their recommendation any State shall issue a license to practise. Examinations should be theoretical and practical, the fee should be twenty-five dollars for each examination and the meetings of the Board should preferably be held in Washington, D. C. The necessary expenses of the examiners could be met from the fees and from a contribution from the American Medical Association. The government medical services would also be willing to detail some men to act in this capacity without expense.

The Neurologist's Art.—Joseph Collins offers the following conclusions: The neurologist's art lies (1) In recognizing that the vast majority of diseases that he encounters can be influenced by treatment; (2) In having in his mind, when face to face with disease whose course he desires to influence favorably, a clear picture of the pathological process constituting the basis of the disease; (3) In appreciating that the successful treatment of nervous diseases requires the most scrupulous attention to detail in the application of measures that experience has shown to be of value; (4) In utilizing judgment and skill in the selection and application of measures that have been found useful, empirically and experimentally; (5) And finally, in realizing from the outset that a disease or disturbance of function which is either the expression of a prenatal defect, or of many years' duration, cannot be overcome in a few weeks, or even a few months of treatment, even though the hand that administers it be both masterful and magical.

New Method of Anchoring the Kidney; a Preliminary Report.—The method of B. B. Davis is thus described: The kidney is well exposed and an incision made through the proper capsule from two cm. below the upper pole to a point two cm. above the lower pole. This incision is placed vertically on the posterior surface near the convex border. The capsule is stripped loose from the kidney substance for a distance of three-fourths of an inch anteriorly and posteriorly to the incision in the capsule. From the upper and lower extremities of the vertical incision a perpendicular incision three-fourths of an inch long is made through the capsule, this giving two flaps of capsule three-fourths of an inch wide by about two and one-half inches long. Next a strip—the thickness of a little finger—of the other border of the quadratus lumborum muscle is split from the remainder of the muscle, the fibers being separated by the handle of the scalpel. This separation extends from the muscular attachment to the twelfth rib downward for two and one-half inches, or the slip in the muscle is made as long as the length of the capsular flaps before described. An artery forceps is passed through the slit in the muscle, made to grasp the free border of the posterior flap of the kidney capsule and then withdrawn, bringing the flap of the kidney capsule through the slit in the muscle. The two capsular flaps are next brought together over the bundle of muscular fibers thus isolated from the border of the quadratus lumborum, and stitched together with a running suture of fine chromicized catgut, the needle being allowed to penetrate the muscular bundle at two or three places. The lumbar wound is next closed by tier sutures of catgut, the skin wound being closed with horse-hair.

An Analysis of Fifty-two Cases of Tetanus Following Vaccinia.—R. N. Wilson discusses this question with special reference to the source of infection. His statistics cover the period from 1839 to 1902. An elaborate table is given with details of each case. He finds that infection has taken place in most if not all cases at the site of the vaccination. The exact time of infection and the exact means are impossible of absolute and scientific proof; and that the grouping of a large number of cases in a certain locality, and following the use of a certain production of vaccine virus, would tend at first sight to speak for a primary infection, carried in with or by means of the vaccine virus into the system. On the other hand a secondary infection, and one occurring, as a rule, about the time of the acme of the vaccinia, is indicated by the otherwise discordant chronic incubation period and acute symptoms, by the almost uniformly fatal termination, by the severity of the course of the disease, by the millions of normal vaccinations with the same virus, by the simultaneous deaths from tetanus known to be due to other causes, by the diminution in the number of such cases now that continued aseptic care is more generally exercised, by the fact that in every case in which particulars are known over-abundant opportunity was offered for such secondary infection, and, finally, and most important, by the absolute failure of all bacteriologic and inoculation experiments on the lower animals and man to indicate the presence of the tetanus microorganisms or their toxin in the virus. As to the results of treatment he finds that out of thirteen patients treated with antitoxin ten died and three recovered (mortality 76.9 per cent.). In all of these cases the usual treatment was employed in conjunction with the serum. Seven patients recovered under the customary routine of chloral, bromide, opium, cocaine, and more rarely physostigma; and thirty-two died (mortality without antitoxin 82 per cent.). Of the entire number of cases eleven recovered and forty-one died (mortality 78.8 per cent).

New York Medical Journal, May 12, 1902.

A New Study of Mitral Obstruction with Illustrative Cases.—T. E. Satterthwaite finds that mitral obstruction is more common in females than in males, and is generally fatal before the fortieth year. There is apt to be a marked contrast between a strong cardiac impulse and a feeble radial pulse. A true presystolic murmur appeared in 15 per cent. of his cases, generally of a loud rasping or sawing quality, sometimes "gushing" or whining. Adiastolic murmur occurred in 40 per cent. of the cases. He finds that these latter murmurs are best heard over a rather limited area, somewhat oval in form, having for its center an area between the fourth left space, inside the nipple and the apex, and extending an inch or so to the right or the left. Occasionally this murmur is heard best as low as the fifth, sixth, or even seventh left space; more rarely it is heard as high as the second left rib. In 10 to 35 per cent. there was a thrill over this area. The first sound at the apex is short and abrupt, while the second pulmonary sound at the base is usually intensified. Occasionally a murmur is heard with the second sound over the left appendix auricular. At first there is hypertrophy of the left ventricle; then atrophy thereof with hypertrophy of the left auricle; then follow dilatation and hypertrophy of the right heart. Mitral insufficiency must, to some extent, accompany mitral obstruction. In distinguishing the presystotic murmur of mitral obstruction from the Flint murmur of aortic insufficiency, we should rely on the "[illegible] heart" and the strong impulse of the "Cor[illegible]" of [illegible], rather than [illegible] [illegible]. Because there is both [illegible] [illegible] and [illegible] [illegible], a differential diagnosis is impossible, with the [illegible] as [illegible] as [illegible] [illegible].

Medical News, May 10, 1902.

Empyema of the Gall-Bladder.—Lewis W. Hotchkiss says that in all cases of acute suppurative cholecystitis as well as in the chronic empyemata, surgical treatment is clearly indicated and is often imperative. There is great danger in expectant [illegible] and medical treatment, [illegible] [illegible] as to [illegible] [illegible] peritoneal infection. In cases of acute cholecystitis in a relatively healthy gall-bladder, clinically [illegible], with more or less peritoneal irritation, prompt [illegible] [illegible] [illegible] [illegible]. Early operation should be done to prevent the spread of inflammation to the adjacent peritoneum. Acute cholecystitis in an already contracted gall-bladder, which has been the seat of previous inflammatory attacks, offers some difficulty in early diagnosis on the absence of a tender and palpable tumor. In these cases cholecystectomy is to be employed as a rule, although [illegible] is proper in carefully selected cases. In cases of [illegible] of the gall-bladder, stones in the cystic duct and pus in the bladder cavity, with [illegible], demand incision and drainage. In some cases a cholecystectomy may be necessary, as when the stone is so firmly wedged in the cystic duct to allow its removal by expression into the gall-bladder. Early cholecystostomy, when the disease is limited mainly to the gall-bladder, is the safe and effective procedure. Delay is often dangerous and should not be considered.

Sudden Death in Aortic Stenosis.—James M. Anders warns against making the diagnosis of aortic stenosis without due caution and reserve. The number of proved cases of this affection is small because of the rarity of the concurrence of all of the characteristic signs. These signs are: A small, slow and somewhat tense pulse, a systolic thrill, an enlargement of the left chamber, a harsh and musical systolic murmur over the aortic area, and a feeble aortic second sound. A case reported was that of a woman of forty-four years who exhibited all of the classic signs. The intensity of the aortic second sound was greatly increased; this was probably due to the dilatation of the aorta above the valves. The fact of the accentuation of the aortic second sound and an abnormal area of dulness about five cm. in its greatest diameter and extending upward and to the right from the base of the heart led to the opinion that dilatation of the aorta existed, with probable involvement of the sinuses of Valsalva. The patient died suddenly during sleep. Autopsy showed the aortic cusps and the aortic segments to be the seat of marked atheromatous change; the segments were united, puckered, and contracted, and of calcareous consistence. These changes caused decided narrowing of the orifice and prevented the cusps from falling back into the sinuses of Valsalva during the systole, and offered obstruction to the blood-stream. Above the aortic segments, and including the sinuses of Valsalva, the aorta was dilated, and the orifices of the branches of the aorta were distinctly atheromatous. The dilated part involved about six cm. of the aorta and showed an aneurysm-like pouching. For some distance above the dilatation the caliber of the aorta was considerably diminished. The mitral valve and those in the right heart were normal. The diminished caliber may have been due partly to the closing of the [illegible] and lessened volume of the blood entering the aorta owing to the existence of the constricted aortic orifice.

The Philadelphia Medical Journal, May 10, 1902.

The Justus Test for Syphilis, with Report of Cases.—W[illegible] E. H[illegible], Jr., concludes that although the number of cases which he reports is very few, there are enough negative results in the group of [illegible] to show that the test is neither [illegible] [illegible], and, moreover, the one positive result among the nonsyphilitics detracts even more, because the failure to get a reaction [illegible] mercurial treatment will soon be proven a [illegible], but to condemn a nonsyphilitic to years of unpleasant treatment, and to the belief that he has had the disease, is inexcusable.

Value of the Justus Test, with Report of Cases.—Henry Tucker states that the test is based upon the fact that mercury given either by inunction or intravenous injection, or by [illegible] will cause a diminution in the hemoglobin of the blood. The hemoglobin is said to be rapidly restored to the normal in the healthy, but more slowly in the syphilitic. In the cases studied by the writer, after the first examination for hemoglobin, all the patients were given an inunction of one drachm of mercurial ointment, and were re-examined within from twenty-four to thirty hours after the drug had been given. The hemometer of Fleischl was used in the first few cases and afterward Dare's hemoglobinometer. The writer is convinced from his experience that Justus' test has no practical value in the differential diagnosis of syphilis, since the reaction occurs with an almost equal degree of frequency in the nonsyphilitic conditions with which syphilis may commonly be confused.

The Kidney Complications of Typhoid Fever.—James [illegible] [illegible] has found the following renal complications of typhoid fever: Albuminuria, acute nephritis, hemorrhagic nephritis, suppurative nephritis, persisting chronic nephritis, hematuria. Albuminuria occurs in a large percentage of typhoid patients. Early, it is merely febrile; later, and larger in quantity, it is both febrile and toxemic. It may appear during the first few days, but usually during the second week. It usually disappears early. The earlier it appears the longer it lasts. The greater the quantity the more serious it is. Acute nephritis occurs with varying frequency. It is usually acute parenchymatous and may be hemorrhagic. It may occur at any time during the course of the disease. Uremia is very rare. Its appearance is generally of bad prognostic significance, as it means either intense intoxication or lessened resistance. There appears to be no sharp line between ordinary acute nephritis from the hemorrhagic, except the larger quantity of blood. As to suppurative nephritis, cases with necrotic areas and actual abscess formation are recorded a number of times. The typhoid bacilli are found in the pus areas. In the urine are large numbers of mononuclear leucocytes. In cases of typhoid fever with previous chronic nephritis the prognosis is very bad. Hematuria has been reported in a case in which post-mortem examination showed the kidneys to be only congested.

American Medicine, May 10, 1902.

Palmar Reflex.—John H. W. Rhein, while studying a case of hemiplegia recently observed what seemed to be a hitherto undescribed reflex. Slight irritation of the palmar surface of the hand with the point of an esthesiometer was followed by an extension of the hands and fingers. Sometimes only the hand was extended, sometimes only one or more of the fingers. The arm was not drawn away in a manner analogous to the withdrawal of the foot when the plantar surface is irritated. The writer has observed this reflex in one other case of disseminated sclerosis.

Gastrotomy for Removal of a Watch.—This case came under the care of Herman Mynter. The patient was a young man of twenty years. A week before seeking medical assistance he had accidentally swallowed a cheap watch. It measured 1¾ inches in diameter, 2 inches through the stem, and 1⅜ inches in thickness. He had suffered no inconvenience from the accident. An x-ray examination showed the watch plainly in the fundus of the stomach. As the watch did not pass from the stomach, although he was fed on dry diet and directed to lie on the right side, gastrotomy was performed and the watch removed. It was completely covered with verdigris and [illegible] [illegible]. The patient was nourished by rectum for six days, and on the thirteenth day he left the hospital with the wound healed, and able to eat solid food.

A Case of Tuberculous Salpingitis.—Howard S. Dittrick reports this case. The patient, a married woman of twenty-[illegible] years, complained of dull pain in the lower abdomen extending down into the thighs, backache, a leucorrheal discharge, and constipation. The right tube and ovary were somewhat enlarged and adherent. The left tube and ovary were small, irregular and adherent. There were a few moist râles over both apices of the lungs. Tubercle bacilli were found in small number in the sputum. Abdominal section was performed and both tubes and ovaries and the appendix were removed. The patient was discharged much improved. The presence of tubercle bacilli was demonstrated in the tissue of the Fallopian tube and cultures were made from the pus there contained. The disease was also reproduced in a guinea-pig which had been inoculated from the primary lesion.

Prager medicinische Wochenschrift, April 17, 1902.

Sugar-Coated Heart.—Hermann Eichhorst reports a case of this rare condition, which may be regarded as analogous to the sugar-coated liver of Curschmann. The patient, a woman forty years of age, had had attacks of marked cardiac insufficiency for six months previous to her death. These attacks increased in severity and duration, so that upon admission to the hospital the radial pulse was continuously over 140 per minute, and edema, dyspnea, and cyanosis were permanent. The administration of digitalis improved somewhat the action of the heart, but the other symptoms became progressively worse and death soon took place. Upon autopsy a clear yellowish fluid was found in the pericardial sac. The pericardium was practically normal, but the epicardium was changed into thick, firm, marble-white tissue, which gave the heart the appearance of being sugar-coated. The heart itself was nearly double the normal size, but no pathological alterations were found in the myocardium. There is no doubt that the symptoms of cardiac insufficiency were due to a direct mechanical interference with the heart's action by the thickened and firm epicardium. The patient was an alcoholic, and it is possible that the etiology of the condition may be thus explained.

Potassium Nitrate and Nitrite in Chronic Increased Arterial Tension.—Lauder Brunton emphasizes the value of nitrates and nitrites in the treatment of chronic increased arterial tension. The chemically pure nitrates as at present sold in the shops when prescribed alone do not give nearly as good results as the unpurified product, since the latter contains nitrites in addition to the nitrates. This fact was first made apparent to the author in the treatment of a case of chronic increased arterial tension, in which he prescribed potassium bicarbonate and nitrate. At first the nitrate was procured from a powdermaker in the form of ordinary saltpeter and a satisfactory result was obtained. Later the nitrate was procured from a druggist, who charged nearly three times as much therefor as did the powdermaker, yet when so compounded the prescription immediately lost its efficiency. This reason of this was not at first apparent. Subsequently it was suspected that it was due to the absence of nitrites in the chemically pure nitrate obtained from the druggist. Sodium nitrite in small doses (.03) was then added to the latter prescription and the original beneficial effect was immediately produced. Thus the especial value of the nitrites in this condition is amply demonstrated, and it is certain that they should always be combined with the nitrates when the latter are given in chemically pure form.

The Multiplicity of the Toxins Produced by One and the Same Bacterium.—A. Charrin draws attention to the fact that in explaining the symptom-complex of the various infectious diseases it is necessary to consider the various toxins produced by the causative microorganism. It is certain that we can no longer explain such a symptom-complex on the supposition that it is produced by only a single toxin. Advances in bacteriology have shown that any given pathogenic microorganism produces a variety of toxic products, and as our knowledge along this line widens these products increase markedly in number. The author's researches with the bacillus pyocyaneus have shown that this microorganism produces a variety of products, such a various pigments and different ammonia and amide combinations, all of which possess pathological properties. Furthermore, the effects of the latter, volatile products appear sooner after infection than do the effects of the toxin proper and it seems certain that the action of the former increases the susceptibility of the body to the toxin proper. The development and number of these pigments and volatile products depend not so much upon the particular variety of bacillus pyocyaneus used as upon the media employed for its growth. The immunity produced, however, is always due to the action of the toxin proper. The accessory products, so to speak, appear to be due to special properties of the microorganisms, which are developed as the result of growth upon different media and under various external conditions. In this manner the diversified symptom-complex produced by infections with one and the same bacterium may be easily understood.

Berliner klinische Wochenschrift, April 21, 1902.

Diabetic Leucomains.—R. Lepine, in confirming the observations of Leo, has been able to extract from non-diabetic urines (especially pneumonic) substances which, upon inoculation, possess a diabetic power. Following the methods of A. Gautier, the author has obtained from blood leucomains which, when dissolved in water and inoculated, in small amount, subcutaneously into guinea-pigs, give rise to a more or less permanent glycosuria. Recent experiments have shown that the subcutaneous inoculation of an alcoholic extract of five grains of normal dog's blood produces only a very transient glycosuria, while the inoculation of a similar extract made from the blood of a depancreated dog causes a glycosuria of several days' duration. This result favors the idea that under normal conditions the pancreas, at least to a certain degree, destroys diabetic toxins and that, when the action of the pancreas is inhibited, such toxins, accumulate in the system.

Coincident Acute Polyarticular Rheumatism and Typhoid Fever.—P. K. Pel reports a case in which these two diseases were simultaneously existent. In October, 1901, the patient suffered from a pronounced attack of polyarticular rheumatism, which, however, promptly yielded to salicylate of sodium. The latter part of November he developed a typical clinical typhoid fever, which showed the characteristic typhoid roseola. Two weeks after the beginning of this disease a polyarticular rheumatism appeared, which, however, quickly subsided, as before, under the administration of the salicylate. The course of the typhoid was not influenced by the rheumatic attack. A positive Widal reaction was never obtained, although repeatedly looked for throughout the disease. The diazo-reaction was likewise negative. Notwithstanding these facts, the author regards the diagnosis of typhoid fever as certain. Cases are mentioned within his experience of undoubted typhoid in which the Widal and diazo-reactions were permanently negative.

The Clinical Importance of the Personal Factor in Disease.—Dyce Duckworth thinks that in these latter days too little consideration is given to the personal factor in disease. This is shown by the fact that the old doctrines of the several diatheses are now either totally ignored or regarded as misleading. The laboratory has come into undue prominence and many false theories are emanating therefrom. Thus we are told, from the laboratory, that scrofulosis is always a tuberculous process, while it is certain, from clinical observations, that many persons are scrofulous all their lives and yet never become tuberculized. The existence of a rheumatic and gouty diathesis is certain and should be given due consideration in the treatment of disease. Of course, laboratory aids are not to be entirely ignored, but the rising generation of practitioners should be impressed with the fact that the knowledge to be gained from an accurate conception of the specific tissue qualities of each individual is of prime importance in the correct diagnosis and treatment of disease.

Münchener medicinische Wochenschrift, April 22, 1902.

Action of Iodine in Arteriosclerosis.—Jodlbauer reviews the literature upon this subject and comes to the conclusion that the beneficial results of iodine in arteriosclerosis are primarily due to the vasodilating properties of this drug. In arteriosclerosis the increased arterial pressure gives rise to a damming back of the blood in the heart and venous system. The tissues are, therefore, supplied with a smaller quantity of arterial blood than under normal conditions. By dilating the arterioles iodine relieves this congestion and thus increases the nutrition of the tissues; the increased supply of blood also favors the action of the lymphatic system and thus accelerates absorption. Furthermore, the coronary arterioles are likewise dilated, and thus the nutrition of the heart is directly benefited.

Recurrent Radial Pulse.—Under this name Arthur Meyer describes a phenomenon which, he thinks, has not been previously mentioned. If the first, second and third fingers are placed upon the radial artery so that the pulsations of the same are perceptible to all three, and more pressure is exerted with the middle finger than with the others, the pulsations of the artery are less perceptible to the first and third than to the middle finger. If now slight pressure is exerted by the peripheral finger, the middle finger fails to perceive the arterial pulsations, notwithstanding that they can still be plainly felt by the peripheral finger; in many cases the pulsations of the artery are visible on the distal side of the peripheral finger, showing that the pulsations are conveyed from the periphery *toward* the heart. The explanation of this phenomenon is the backward flow of the blood from the ulnar artery to the radial through the arcus volaris. This phenomenon may be observed under normal as well as pathological conditions and hence is of no diagnostic value.

The Diagnostic Importance of Cutaneous Angioma.—Rosenbaum reports the results of a series of observations, which were instituted in order to ascertain the relations between carcinoma and cutaneous angioma in so far as the presence of the latter signifies the existence of the former. Four hundred persons were examined, of whom 308 showed cutaneous angiomas in greater or less number. Of these persons fifty-three were under and 255 over thirty years of age. Of the ninety-two who did not have cutaneous angiomas sixty-five were under and twenty-seven over thirty years of age. Among the 400 persons there were three in whom a diagnosis of carcinoma was certain and four in whom it was extremely probable. All of these seven possessed cutaneous angiomas, varying in each case from nine to forty-two in number. All of these seven were over forty-eight years of age. Further observation showed that frequently the number of cutaneous angiomas in the non-carcinomatous exceeded that in the

[illegible]

The Use of Quinine in the Local Treatment of Wounds. —[illegible] Such dressings, however, should not remain in situ longer than twenty-four hours, as they produce a coagulation of the albumen, and unless removed might give rise to a coagulation necrosis. The local use of quinine is especially applicable to fresh wounds.

French Press.

Phototherapy in Relation to Cutaneous Tuberculosis.—Leredde has treated and cured by phototherapy many patients affected with tuberculous lupus who were considered incurable as far as other methods were concerned. These patients had almost all been suffering from the disease for from six to fifteen years and had been treated in the most radical manner and for long periods of time. All possible methods had been tried. Aside from ablation, phototherapy is the shortest method of treating lupus vulgaris and lupus erythematosus. It gives a proportion of cures of which no other method is capable. Nevertheless, in a case of tuberculous lupus, when taken at the very beginning, ablation is always preferable. In the vegetative forms the employment of potassium permanganate is useful in facilitating the penetration of the chemical rays. Phototherapy is regularly used in lupus of the extremities and of the trunk.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, April 24, 1902.

Saturnine Gout.—Widal states that this affection is rare. He describes a patient, a man of fifty-seven years, who has been a painter since the age of eleven. The patient has multiple tophi in his fingers and ears. His health is excellent and, excepting the crises of gout from which he suffers, he is quite comfortable. There is no paralytic manifestation nor any anæmia. Besides, although he has had gouty crises for thirty-years, he shows no visceral alteration nor any sign of nephritis. The classical symptoms of lead gout are given as absence of tophi, anæmia, early visceral lesions, and nephritis. The father of this patient had suffered from lead poisoning. The theory that gout is caused by a renal lesion is not always borne out clinically, as many gouty patients have no nephritis and many nephritics are not affected with gout. The hepatic theory seems the most plausible. There are disturbances of nutrition in the liver. The prognosis in this disease is excellent.—*Journal des Praticiens*, April 19, 1902.

Femoral Hernia of the Cæcum and of the Right Angle of the Colon; Strangulation for Fifteen Days; Cœliotomy; Death.—[illegible] reports this case. The patient, a porter forty-seven years old, had suffered from a large femoral hernia for years. It was difficult to hold with a truss. The hernia became irreducible and symptoms of subacute intestinal occlusion appeared. There was no movement of the bowels, but there was an escape of gas and some vomiting. These symptoms persisted for eight days and then the hernia became more painful; at the same time the emission of gas ceased completely and the vomiting increased. Hernia of the cæcum was diagnosed, and operation was undertaken. The [illegible] hernia was reduced after the femoral ring had been cut, as it had been partly responsible for the strangulation. The cæcum was supported in the hernial orifice with a view to an artificial anus if that should prove necessary. Iodoform gauze was used as a drain. That evening 800 grams of artificial serum were given. The following afternoon the patient died. Autopsy disclosed the cæcum and ascending colon much distended. Following the course of the latter it was found that the cæcum and the right angle of the colon were [illegible] adhesions with the [illegible] between them.—*Lyon Médical*, April 20, 1902.

Treatment of Severe Puerperal Hemorrhages.—G. K[illegible] says that the general phenomena which the [illegible] after hemorrhage are related to [illegible] and to disturbances of the nervous system. The patient is pale [illegible] the lips and the extremities are cold. The blood [illegible] shows a considerable decrease [illegible] of red blood corpuscles. Nevertheless, [illegible] restoration is possible [illegible] a patient recovered after the number of red corpuscles had been reduced [illegible] 1,400,000. The [illegible]. The patient is depressed and suffers from "air hunger." The pulse is rapid [illegible]. It is small and thready, and [illegible]. Bulbar and cerebral [illegible]. The patient [illegible]. The patient should be laid flat without pillows and with the head on a level with the thorax and extremities. The Trendelenburg position is [illegible]. The extremities may be bandaged in order to send the blood to the brain. The peripheral nervous system is stimulated by flagellation of the body surface, frictions with alcohol, by the use of ammonia, by inhalations of [illegible] ether, by the application of mustard plasters to the lower extremities, and by [illegible]. Heat is absolutely necessary in the treatment of hemorrhage. Inhalations of oxygen are given. If syncope still persists in spite of this treatment, artificial respiration must be resorted to. Subcutaneous injections of [illegible] of camphor give tone to the heart muscle, and artificial serum may be injected to raise arterial pressure; if death is imminent it may be given intravenously. It is exceptional to see a patient recover who presents delirium, incontinence of urine and fæces, and bulbar symptoms in general. After the syncope has been overcome the patient should have absolute repose. Heat must be applied and diluted alcohol may be given in small doses. Coffee and the tincture of digitalis are indicated. The feedings should be frequent and of small quantity. Iron and strychnine should be administered, and when the nervous system demands it, arsenic.—*La Presse Médicale*, April 5, 1902.

The Journal of Tropical Medicine, April 15, 1902.

Filariasis in St. Kitts, W. I.—George C. Low says that filarial diseases are very prevalent in the island, the chief type being filarial lymphangitis, locally known as "fever and ague" and "rose," very few of the white inhabitants having escaped attacks at some period or other of their lives. The spread of the disease by means of the culex fatigans mosquito has been proved beyond a doubt. The prevention of filariasis consists in the use of the mosquito net, the destruction of breeding grounds in tanks and other receptacles, and in the substitution of dry earth closets for the privy system now in use. St. Kitts has awakened to a sense of its danger and has taken up the subject in earnest. It will be an interesting study in the course of the next generation to watch the general reduction and stamping out in the island of this loathsome complaint.

New Growths in Tropical Countries.—A. B. Dalgetty considers new growths to be much less common among the less civilized races, and wonders whether the presence of malaria has anything to do with it. In tropical countries malaria is ubiquitous, and every one suffers from it more or less. He has never yet seen a case of malignant disease of the mamma in a native of India. The reason for this is a mystery, but he calls attention to one or two points in which the habits of the natives contrast sharply with those of the Western races. In the first place, a woman's dress consists simply of a cotton cloth passed around the body and pulled up over head and shoulders, so that no pressure is exercised on the breasts. In the second place there is the custom of oiling the body, and in the third place mothers suckle their children eighteen months and longer, so that the lately formed cells of the gland undergo a gradual and complete devolution instead of their function being suddenly checked while they are still in full activity. The breast is literally sucked dry. Such a gland would appear less liable to undergo perverted action than a gland arrested while its function is still in full force.

In Pelvic Operations it is very necessary, if we are dealing with pus cases, which never stand anæsthesia and shock at all well, to seek first for the most rapid mode of incision and drainage. In the majority of cases the vaginal route will be the best for this purpose, even if a secondary operation may be required later.—*Southern Clinic.*

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Sixteenth Annual Meeting, Held at "Marlborough House," Atlantic City, N. J., April 29 and 30, 1902.

THE PRESIDENT, WILLIAM T. BEFFIELD, M.D., IN THE CHAIR.

The Technique of Prostatectomy.—Dr. JOHN P. BRYSON of St. Louis read this paper, reporting several cases and presenting to the Association a large number of specimens. After considering the etiology and pathology of the vesical conditions in prostatism, he stated that an adequate technique must include the removal not only of the urinary, but equally that of the circulatory obstruction and that an operation that dealt only with one of these was incomplete. With such modifications as seemed to be demanded by special conditions, the technique was as follows: The anæsthetized patient, whose perineum and abdomen had been prepared as for cæliotomy, is placed in a lithotomy position, a catheter introduced, the bladder irrigated with warm boric acid solution, and filled with warm salt solution to a point just below that which produces distension reflex. A broad grooved staff is introduced and a free perineal incision made in such a way as to open the urethra just in front of the apex of the prostate. Most frequently the bulb is split, in which case a vessel is clamped or the oozing is staunched by a catgut suture *en masse.* The knife, after entering the groove of the staff, is pushed backward far enough to incise the ring at the apex of the prostate, which is one of the least distensible parts of the duct. The forefinger follows well into the prostatic urethra, usually tearing it somewhat, and the staff is withdrawn. The finger quickly exposes the prostatic urethra, and ascertains whether the vesical outlet can be reached; after which the forefinger of the right hand in the rectum permits bimanual examination of the part of the prostate within reach. Guided by the finger, a blunt instrument is now passed into the urethra, and made to puncture from the urethral side the most prominent part of the mass. This puncture is always made in the power posterior quadrant, and the instrument is pushed well into the swelling. On its withdrawal the finger tears its way into the center of the mass which, even in fibrous prostates, is comparatively friable. The mass is now opened through to its capsule, the finger-swept round its periphery without tearing the prostatic capsule or fibrous sheath of the gland. In the meantime the urethra is felt to tear longitudinally. After the lobe has been loosened all around, there remains the attachment to the urethra, in detaching which care must be had not to take away too much of the sides nor any of the roof of the urethra. The floor may be disregarded if necessary. The hypertrophied lateral lobe is then removed, to do which one has often to go well up behind and beside the neck of the bladder, yet it is possible to do this and keep within the capsule. Very little bleeding follows, but what there is appears to come from the torn mucous membrane, the lower part of which is often brought away. If there is any difficulty in delivering the detached mass, which is very smooth and slippery, an ordinary lithotomy forceps may be employed. If it is too large, it may be broken up with the finger or divided with scissors. This process is repeated on the opposite side, after which a median posterior segment remains to be dealt with. This can usually be done by sweeping the finger from side to side, its dorsal aspect towards the capsule, pushing it backwards in such a way as to detach it well up behind the bladder and roll it downward. One may be surprised to find that he may get behind and excochleate what he had just felt as a pedunculated, intravesicular projection, or a growth *en collerette*, bringing it well down by use of the forceps, apparently without disturbing the fibrous ring at the vesical outlet. Most frequently one finds the attachment of this mass to the urethra quite firm; and, no matter how much care is taken, some of this membrane is brought away. The more the detached mass is rolled downwards by pulling upon its upper surface the less mucous membrane is removed. In some cases the whole of the floor, including the colliculus and veru montanum, has been removed without harm; in fact, in most of these cases this has been necessary, the explanation of which may be found in the anatomical gland, passing from the lateral lobes, and, if there be any, from the median portion, as well as the ejaculatory ducts, unite here and empty into the sulci on either side of the veru montanum, while the colliculus often passes deeply into the tissue; this shows also how it is that those who practice excochleation from the capsular side, find it necessary to make a hole in the urethra at this point, or to cut the pedicle with knife or scissors. Usually now the finger may be passed through the ring into the bladder, which may be explored thoroughly. The cavity is now irrigated with a hot salt solution until the oozing ceases. If the finger be now introduced the floor and the sides of the urethra will be found intact, the latter often hanging loosely against the outer wall or sides of the cavity, from which the growths have been removed. A large cavity is made out, between the lower part of which and the rectum there is felt a thin wall. Into the lower part of this, hinged posteriorly about the ring at the vesical neck, is an irregular flap of mucous membrane, which can be pushed up and back and often made to occlude the vesical outlet. The walls of this cavity feel rough and irregular, and often shreddy; nevertheless, they do not seem to be a poor basis for "taking" of a graft; for it seems that, if properly managed, this tongue of mucous membrane readily becomes attached, behaving subsequently like an autoplastic flap. Care must be taken not to double backward and push this flap into the bladder when the large drainage tube is introduced, the sound edges retracted and the cavity packed with gauze loosely or tightly, as may seem necessary, to provide against subsequent hemorrhage. In packing one naturally takes into account any oozing point usually found about the edges of the mucous membrane.

The Surgical Relief of Prostatic Hypertrophy.—Dr. CHARLES H. CHETWOOD of New York read this paper, drawing the following conclusions, which were based upon his personal observations: Palliative measures should not be persisted in when they fail, after reasonable duration, to produce and maintain an abatement of symptoms. A first infection of the bladder is not alone sufficient excuse for operation, unless palliative measures fail to promptly subdue inflammatory conditions. Recurring infection of the bladder or ascending infection of the kidney is sufficient warrant for operative interference. There is a growing tendency toward earlier operation than was formerly practised. The greater number of cases of prostatic hypertrophy can be satisfactorily reached through a perineal incision. In the large majority of cases, the requirements of any operation upon the prostate consist in the removal of the obstructing area and depressing the bladder opening into the prostate, so that the *bas fond* may be properly drained. In many cases the obstructing area of the hypertrophied gland can be satisfactorily reached and effectually removed through a perineal opening by means of galvano-caustic incisions. Perineal-galvano-prostatotomy is preferable to the Bottini operation on account of its greater accuracy and lower mortality.

Bottini's Operation.—Dr. HENRY H. MORTON of Brooklyn, N. Y., presented a case occurring in a patient, aged seventy-eight years, who for one year prior to the operation had been complaining of tenesmus and frequent and painful urination, and at the time of his admission to the hospital there was complete retention of the urine. At this time the prostate was observed to be

1¼ inches in diameter and the cystoscope revealed an enlarged middle lobe and trabeculated bladder. The urine was acid, cloudy, with a specific gravity of 1015, and showed a purulent sediment, which contained pus cells but no casts. Bottini's operation was performed, three incisions being made, the anterior one being 1 cm., the posterior 3 cm. and the left lateral 2 cm. in length. Catheterization was necessary until the third day after the operation when the patient began to urinate spontaneously. Eleven days after the operation micturition occurred every hour during the day and five times at night, catheterization being performed once daily with a withdrawal of three to four ounces of residual urine. One month after the operation the patient urinated six times daily and four times at night, and although the stream was slow in starting, it was ejected with good force. The cystoscope at this time showed the posterior lobe of the prostate with a cleft in the middle made by the Bottini incision, and the patient continued to be in good general condition, being up and about the ward. Subsequently his appetite and general vitality began to deteriorate and fifty-four days after the operation he died.

A complete autopsy was not permitted, but the bladder was examined and found to be contracted. It contained a small quantity of thick and foul pus, many small necrotic areas were scattered about the surface, and a number of small sacculi, one containing little calculi, were observed. Traces of the posterior incision were very distinct. The interureteric fold of the mucous membrane had been divided, and the middle lobe of the prostate cleft in halves, necrotic areas being visible at the apex of each half. The left lateral incision had not split the prostate, but merely separated the mucous membrane from the superior surface of the prostate, and no trace of the anterior incision was visible. The kidneys were not examined, but as previous urinalyses had revealed the absence of casts, the cause of death was probably cystitis, which had been greatly aggravated by the operation. The middle lobe of the prostate was completely divided into two halves. The reduction in size of the prostate following Bottini's operation probably resulted from the sloughing subsequent to the burning. The difficulties of placing the instrument in a correct position are shown by the fact that the left lateral incision did not divide the left lobe of the prostate as intended, but only lifted up the mucous membrane covering it, while the anterior incision was found not to be made at all. The obstruction to urination was relieved by a single incision through the posterior median lobe of the prostate, and death did not occur until seven weeks after the operation, at which time the relief was complete. The only reasons he was kept in the hospital until his death was for bladder washing and because he had no home, and had he left the hospital as soon as he was able to go after the operation, his case might have been reported as one of complete retention of urine in a man seventy-eight years of age entirely cured by Bottini's operation.

Prostatectomy.—The same author reported the case of a patient aged sixty-two years who entered the hospital suffering from retention of the urine due to prostatic enlargement. Attempts had been made by his physicians to introduce a catheter and a false passage into the prostate had resulted. At this time no instrument could be passed into the bladder and external urethrotomy without a guide was performed. For three weeks subsequent to this the bladder was drained through a 30 catheter, at which time it was removed, but owing to the fact that the patient could not urinate it was again introduced and allowed to remain two weeks longer, at which time prostatectomy was performed. The method employed was a suprapubic cystotomy to depress and hold prostate, and the perineal wound was used to shell prostate out from the capsule. No difficulty was experienced in enucleating three tumors one-half to one and one-half inches in diameter, and there was no hemorrhage following the operation. Drainage was obtained through perineal and suprapubic tubes. Patient did well for three days, during which time the drainage was perfect, but later he developed uremia and died ten days after the operation. The autopsy showed suprapubic wound recently infected, the cavity from which the prostatic tumors had been removed was healthy in appearance, and indicated that it would have healed entirely by granulation. The obstruction to urination had been entirely removed by the enucleation of the prostatic tumors.

Removal in Toto of All Three Lobes of the Prostate by Suprapubic Cystotomy.—Dr. Charles L. Gibson of New York presented the specimen, which was removed from a patient sixty-two years old, who was admitted to the hospital in July, 1901. History of increasing obstruction of urine for past six years. Urine frequently dribbled away. Examination per rectum showed a considerable degree of enlargement of both lateral lobes. There were 15 ounces residual urine obtained on several occasions. Moderate cystitis. No evident kidney lesion. Prostatectomy by the Alexander operation was undertaken, but the first step, however, revealed the bulging of the prostate into the lumen of the bladder so distinctly that he determined to remove the enlarged portions by this direct approach. The vesical mucous membrane was incised over the urethral orifice and he then found that his finger could be easily swept all around the prostate, so, in a few seconds, he brought out the whole prostate *en masse*. The urethral outlet must have been avulsed, but of this he was not aware, so the prostate was simply shelled out without any force and without any bleeding. The operation was completed by adding a perineal boutonnière for drainage. The result promised to be favorable, as there was no reaction. On the fourth day the dressings were changed, the bladder washed out, and the patient's condition appeared to be admirable, with a normal temperature and a free secretion of urine. Yet, six hours later the patient died without any particular manifestations. No autopsy.

The case was presented not to recommend that the prostate should be removed *in toto* with the necessary drawback of destroying the urethral outlet, but for the purpose of emphasizing how easily the prostate, or portions of it, can be removed without destruction of tissue or hemorrhage, provided one clearly enters the essential line of cleavage.

Dr. Eugene Fuller of New York said that during the last one and a half years he had performed twelve perineal prostatectomies with but one death, which occurred from delirium tremens. The oldest patient was eighty-one years and had atheromatous arteries and a mulberry calculus in his bladder, to remove which he was compelled to make a suprapubic opening. Another patient had tuberculosis of one lung, and so spinal anesthesia was given with good results, although the patient died seven or eight months after the operation, from progressive tuberculosis.

Dr. Francis S. Watson of Boston said that in 1888 he made the statement that two-thirds of all cases of prostatic hypertrophy would be found within the reach of the finger after a perineal incision through the urethra; the same statement held good to-day. He did not believe that an elaborate armamentarium was necessary; he used a little instrument, made on the plan of the old gum-lancet, with which the mucous membrane was split, and then the forefinger was utilized in completing the work of removing the prostate.

Dr. George Chismore of San Francisco said that for thirty years he had seen many operations advocated for the relief of this condition, and they had all been disappointing in their results, but of late he thought he would have to change his views. He had had an opportunity of observing eight cases operated upon by Dr. Goodfellow of San Francisco. His method was very simple, and the only instruments used were the scalpel, staff, and volsella. He placed much importance upon the position of the patient, who should be in a strongly flexed attitude, the thighs being flexed upon the chest. He made a median incision, introduced the staff, opened the urethra, and with his finger, with the greatest ease, enucleated the prostate, all within twenty mintes. All eight cases were bad ones, occurring in old men, two being above eighty years. Among this number there were two deaths. In one case there was present an encysted stone, which he had endeavored to remove through a perineal incision, but failed; he, therefore, made a suprapubic incision and removed a stone not larger than the end of the thumb, which was encysted. This patient died from the effects of the abdominal wound. The post mortem showed the prostatic urethra practically well. The second case was a patient over eighty years. During the operation an opening was made into the rectum, causing the patient's death thirty days after.
